Abstract: In the Cerrado-Amazonian ecotone in the State of Mato Grosso, intensely altered by anthropic action, the knowledge and processes of energy conversion and energy balance are still incipient, making the monitoring and modeling of diffuse radiation essential for several applications. The objective of this study was to evaluate the seasonality of the diurnal evolution and estimate the hourly diffuse radiation (H_d^h) incident radiation in the horizontal plane, between June 2011 and October de 2016. The instantaneous measurements (5 minutes) of diffuse radiation underwent geometric, astronomical, and anisotropic corrections, with subsequent hourly integrations. The seasonality of diffuse radiation and its radiometric fractions was evaluated. The estimates were made considering total and seasonal data groupings (water stations in the region) and in different cloudiness classes (atmospheric transmissivity index - K_T^h). The diurnal behavior of diffuse radiation (H_d^h) was similar to that of global radiation and at the top of the atmosphere, with maximum values at solar noon. The correlations between K_d^h and K_T^h showed third-order polynomial behavior, with maximum observed values of K_d^h ranging from 0.8 to 0.9, for K_T^h less than 0.2. Estimation equations based on radiometric fractions underestimated the values of diffuse radiation, with a better performance presented by models adjusted in annual data groupings. Among the parameterized models for estimating diffuse radiation obtained in the literature, those calibrated regionally in this study, together with those developed for tropical regions, presented better statistical performances.

Keywords: atmospheric transmissivity coefficient; radiometric fractions; estimation models; sky cover

1. Introduction

Brazil is in full technological development in the areas of renewable energy (photothermal and photovoltaic conversion, biomass and biodiesel), agriculture (increased efficiency based on the physical and physiological properties of crops and animals), civil construction (construction materials, micrometeorological aspects), among others. The need to supply energy on an ever-increasing scale, and at the same time economically and sustainably, together with the profile of the high national agrosilvopastoral potential, make up a growing demand for knowledge of seasonal variations in solar radiation levels, considering the spectral and atmospheric attenuation components in the Brazilian territory.

The temporal variation of the amount of solar radiation incident at any location on the Earth's surface depends on astronomical, geographic, and atmospheric factors. The main variations in the seasonal levels of each component of solar radiation originate from the interaction with the atmosphere since some atmospheric constituents are relatively constant in concentration (permanent gases) and others are highly variable in time and space (such as CO₂, methane, aerosols, and water vapor). This variability allows the current composition and concentration of gases in the atmosphere to depend on the geographic position, altitude, and time of year, and therefore influence the processes

of absorption, reflection, and transmission of solar radiation. In turn, among the local characteristics, variations in altitude, inclination (declivity), orientation (azimuth), and shading can affect the energy levels available on the surface, mainly with changes in the geometry of incidence of solar fluxes direct [1,2].

The solar radiation that reaches the earth's surface, called global radiation, can be divided into two components: direct and diffuse, which are transmitted directly through the atmosphere (without attenuation) and are the result of the scattering action in the atmosphere, respectively [3,4]. Measurements of global radiation fluxes are normally obtained in the horizontal plane and available in instantaneous, hourly, daily, monthly, and annual partitions.

Diffusion is a fundamental physics process associated with electromagnetic waves and their interaction with matter, in which particles in the path of an electromagnetic wave radiate their energy in all directions, occurring for all wavelengths within the spectrum electromagnetic. The size of the particles interferes directly in the dispersion process, given by the proportion between the circumference of the particle and the incident wavelength (λ), that is, $x = 2\pi a/\lambda$ (where 'a' is the radius of the particle); in this case, if $x < 1$ (when the particle diameter is less than 10% of the size of the incident wavelength), the dispersion is called selective or isotropic (Rayleigh scattering). For particles whose sizes are similar to or larger than the wavelength, ie, $x \geq 1$, the diffusion is known as non-selective or anisotropic (Mie scattering) [1,2].

In general, diffuse solar radiation levels follow the seasonal behavior of radiation at the top of the atmosphere and vary throughout the year according to local atmospheric conditions (precipitation, cloudiness, aerosols). In Brazil, knowledge of diffuse radiation levels is restricted to locations close to research institutions and/or universities, since the country does not have a solarimetric monitoring network. Recently, the main Brazilian studies focused specifically on the characterization and estimation of diffuse radiation were developed in the Southeast regions [5–12], Northeast [13–15] and South [16–18].

Through a partnership between the Federal University of Mato Grosso and the Laboratory of Solar Radiometry of the Faculty of Agricultural Sciences of UNESP, between 2011 and 2016 global and diffuse radiation monitoring was carried out at the Federal University of Mato Grosso, University Campus of Sinop, standing out as the only site with these observations in the northern region of Mato Grosso [19,20]. The quantification of energy levels of diffuse radiation in this locality, in hourly temporal partitions, in different seasonal periods, in addition to contributing to the understanding of the behavior of local atmospheric phenomena, serves as an environmental indicator since it reflects the air load - aerosols in suspension because of anthropic activities such as forest fires. In addition, it provides data for studies with scientific and socioeconomic development purposes, such as sizing photovoltaic systems.

In this sense, this work aimed to analyze the seasonality and propose statistical models for estimating the hourly diffuse radiation incident on the horizontal, in the Cerrado-Amazon transition, Mato Grosso state, Brazil. For this purpose, the annual and seasonal diurnal evolution of global and diffuse radiation and their radiometric fractions were characterized; in addition, statistical models for estimating hourly diffuse radiation were calibrated based on the atmospheric transmissivity coefficient, and comparisons were made with parameterized models that allow the estimation of hourly diffuse radiation.

2. Materials and Methods

2.1. Characterization of the study region

Global and diffuse radiation data, as well as other meteorological variables used in this study, were obtained from an Automatic Meteorological Station (AMS) in Sinop, Mato Grosso, located at latitude 11.864° S and longitude 55.485° W (altitude 371m) (Figure 1). The evaluated database provides measures between June 2011 and October 2016.

The municipality of Sinop is located in the Mid-North Region of the State of Mato Grosso, has 3,942.23 km² and approximately 130 thousand inhabitants. With a large population growth in the last

seven years (around 20%), the use and occupation of the soil has been intensely altered, with the conversion of vegetated areas into urban and/or agricultural areas, and an increase in the demand for energy and other natural resources [21].

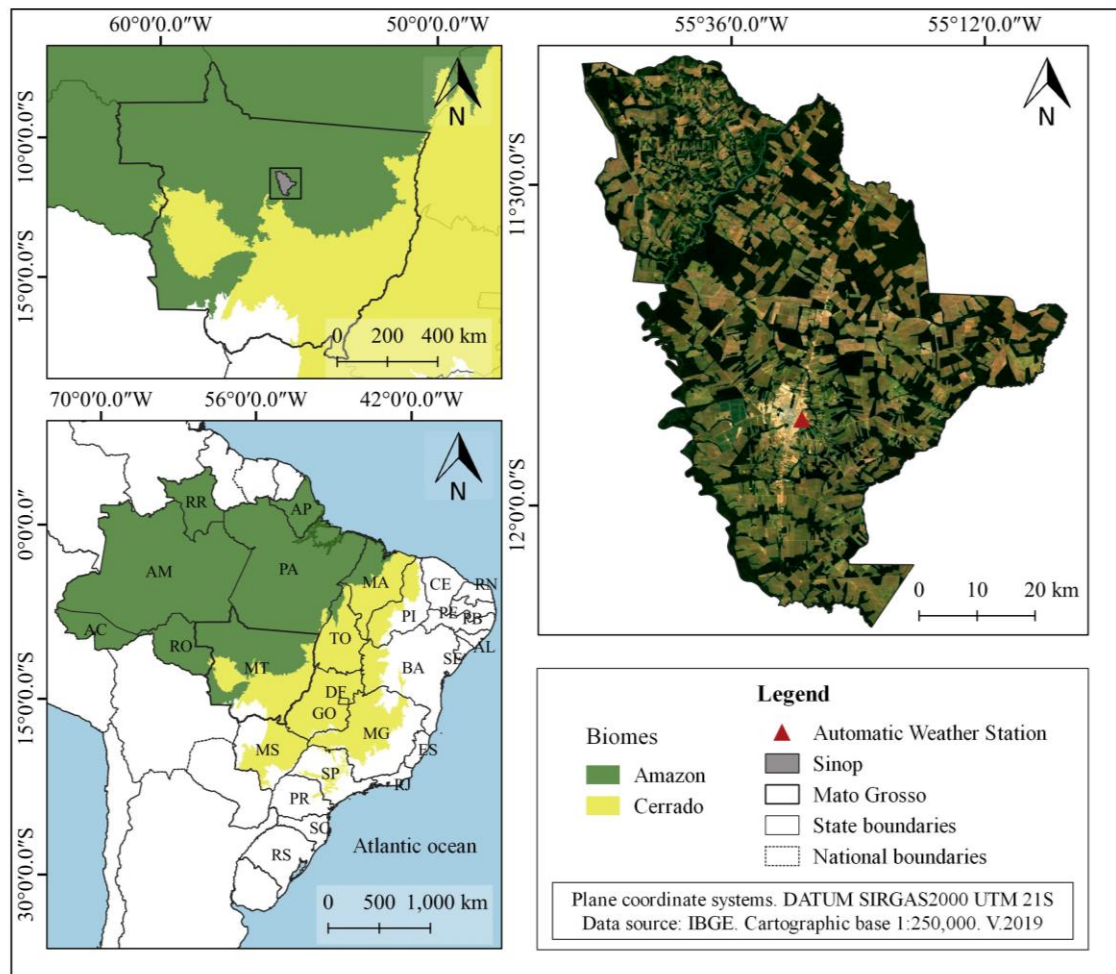

Figure 1. Location of the UFMT Automatic Meteorological Station, Sinop, MT.

According to the Köppen climate classification, the climate of the region is hot and humid Aw tropical, characterized by the presence of two well-defined seasons: rainy (October to April) and dry (May to September) [22]. Average monthly temperatures range between 22.9 and 25.8°C, with an annual average of 24.7°C, and annual precipitation totals are around 2000 mm. There is a high similarity between the average monthly seasonality of meteorological variables recorded during the study period (06/2011 to 10/2016) by AMS UFMT Sinop and the climatological normals of the region (Figure 2). For the representation of the normals, historical series of the Gleba Celeste station was used, which, despite being located in a neighboring municipality (Vera-MT), distant around 80 km, presents the oldest data set in the region (1972 to 2010).

For the observational characterization of the seasonality of global and diffuse radiation, it was decided to group the months according to the rainfall regime of the region, avoiding the seasonal evaluation by the seasons. This type of seasonal analysis is favorable in regions with frequent atmospheric changes resulting from precipitation patterns, as recommended by [23] for analysis of estimates of solar radiation in the Amazon. Souza et al. [22] emphasized that the State of Mato Grosso is representative of great environmental complexity, conditioned, among other factors, to water availability. By observing the behavior of precipitation (Figure 2), the following groupings were

adopted: i: rainy season (December to February); dry (June to August); iii) rainy/dry transition (March to May); iv) dry/rainy transition (September to October).

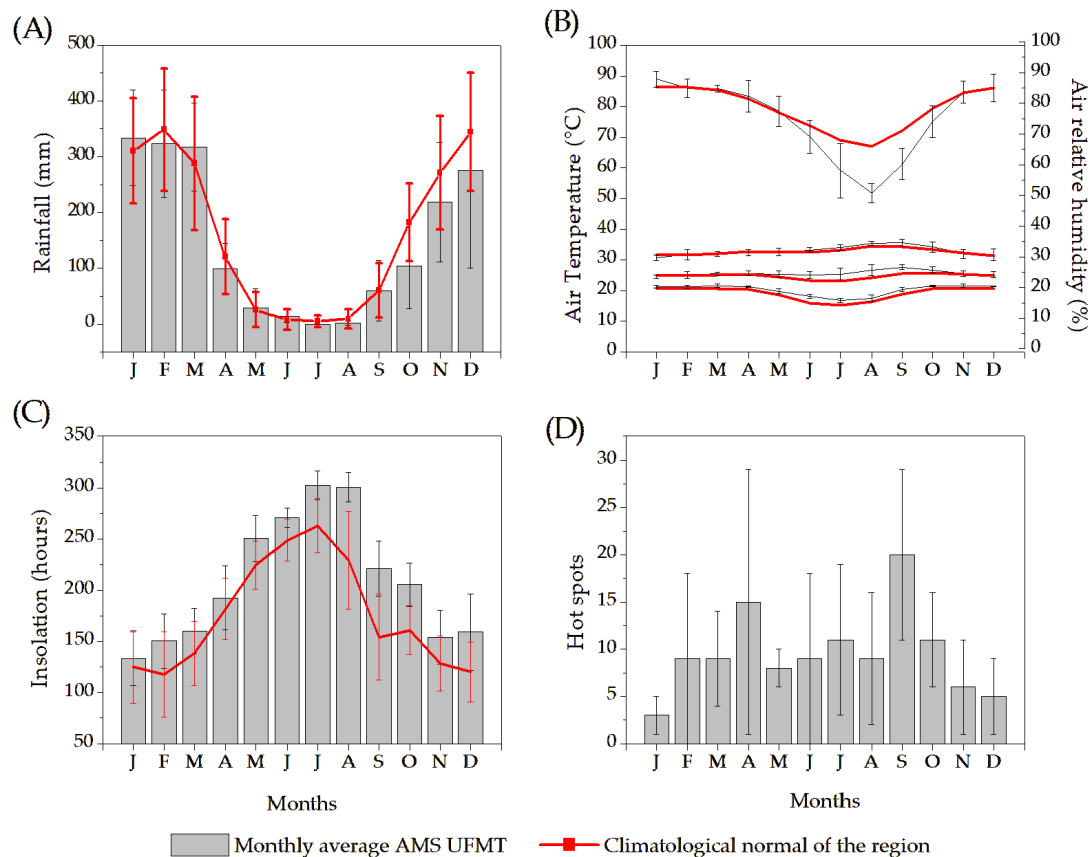

Figure 2. Monthly averages of precipitation (A), air temperature and air relative humidity (B), insolation (C) and hot spots (D) collected in the Sinop-MT region. *Data source: AMS UFMT Sinop (2011-2016) and EMC Gleba Celeste (1972-2010).*

2.2. Instrumentation and data analysis

Instantaneous global and diffuse radiation data (5-minute values) were monitored by Kipp & Zonen CM3 pyranometers, positioned at a height of 1.0 m on a metallic platform (Figure 3). The sensors had a response sensitivity of $\pm 10\text{-}35 \mu\text{V/Wm}^2$, a response time of 18 s, a temperature response of $\pm 1.0\%$ for the range from -40 to 80°C and deviations for the cosine effect of $\pm 2\%$ ($0 < z < 80^\circ$). Data were recorded by a Campbell Scientific model CR1000 datalogger, operating at a frequency of 1 Hz. For the measurement of diffuse radiation, the pyranometer was positioned under the MEO shading ring [24], remaining constantly below the shadow projected by the ring, while for the measurement of global radiation, the sensor remained in full sun. The shading ring used was 0.1 m wide and 0.4 m in radius.

In addition to the pyranometers and MEO shading ring, the following sensors were used: psychrometer with thermometric shelter Vaisala CS 215 installed at 2 m height, Vaisala TE 525 rain gauge at 1.5 m height, heliograph at 1.5 m height, for monitoring meteorological elements air temperature and air relative humidity, precipitation and insolation, respectively.

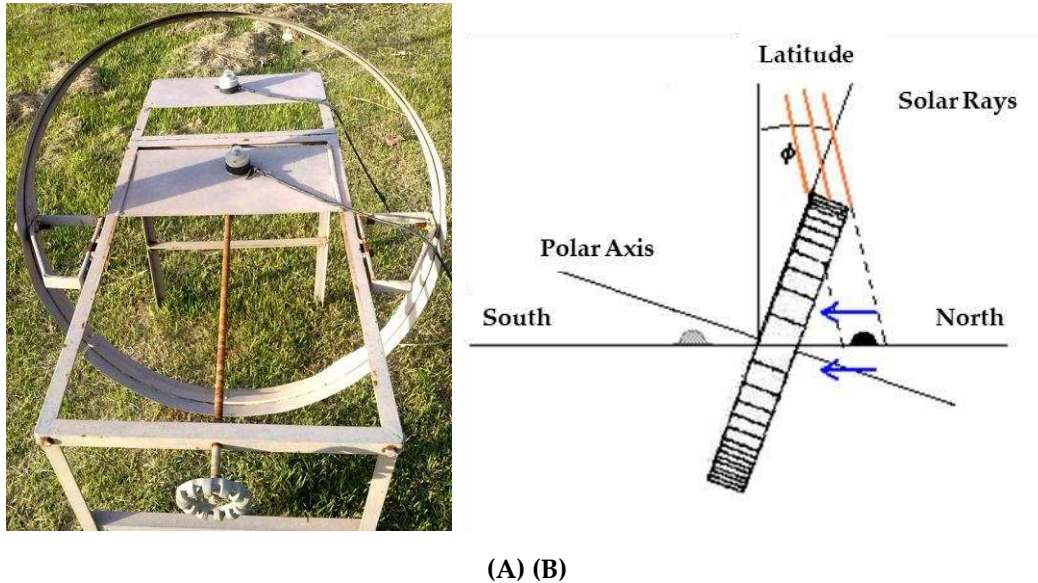

Figure 3. Metallic platform (A) and positioning scheme (B) of the Melo-Escobedo “MEO” shading ring installed in the Automatic Meteorological Station of UFMT, University Campus of Sinop. Adapted from Dal Pai [25].

The solar radiation data were submitted for analysis to observe inconsistencies generated by the collection and storage system. By integrating instantaneous partitions, global (H_G^h) and diffuse (H_d^h) hourly irradiation were obtained. The hourly extraterrestrial radiation (H_0^h) was obtained according to Iqbal [1]. After the hourly integrations, the H_d^h data were submitted to geometric and astronomical corrections proposed by Oliveira et al. [26], by applying the isotropic/geometric correction factor - FC (Eqs. 1 and 2). For the location, FC ranges from 0.99 to 1.00. Anisotropic correction factors proposed by Dal Pai et al. [9,27], are dependent on atmospheric transmissivity (H_T^h) following with the sky cover classification described by Escobedo et al. [28] (Table 1).

$$FC = \frac{1}{1-Fp} \quad (1)$$

$$Fp = \left(\frac{2b}{\pi R}\right) \cdot \cos(\delta) \cdot \left[\frac{\cos(\varphi+\delta)}{\cos(\varphi)}\right]^2 \cdot \int_0^{ws} \cos(\theta z) d\omega \quad (2)$$

where: Fp – represents the portion of diffuse radiation intercepted by the shading ring; b – ring width (0.1 m); R – ring radius (0.4 m); δ - solar declination; w – hour angle; θ_z – zenith angle.

Table 1. Anisotropic correction factors for diffuse radiation by the MEO shading ring method.

K_T^h range	Sky cover	Correction factor
$0 \leq K_T^h < 0.35$	Cloudy	0.975
$0.35 \leq K_T^h < 0.55$	Partially cloudy	1.034
$0.55 \leq K_T^h < 0.65$	Partially clear	1.083
$K_T^h \geq 0.65$	Clear	1.108

Source: Dal Pai et al. [9].

Next, the hourly database was filtered, considering the criteria described by Escobedo et al. [28], where: i) $H_G^h/H_0^h < 0.82$; and ii) $H_d^h/H_G^h < 1.0$. After processing the data ($n = 23,704$ hours of observation of solar radiation), a sample “n” of 22,506 hours was obtained, that is, there was a loss of approximately 5% of the data.

2.3. Radiometric fractions of diffuse radiation

The hourly atmospheric transmissivity coefficients (K_T^h) and the radiometric fractions K_d^h and $K_d^{h'}$ were obtained (Eqs. 3, 4 and 5, respectively).

$$K_T^h = \frac{H_G^h}{H_0^h} \quad (3)$$

$$K_d^h = \frac{H_d^h}{H_G^h} \quad (4)$$

$$K_d^{h'} = \frac{H_d^h}{H_0^h} \quad (5)$$

Subsequently, statistical equations were generated for the correlations between the hourly global radiation diffuse fraction (H_G^h) and the atmospheric transmissivity coefficient (K_T^h) for the annual and seasonal data groupings (four hydro stations). In this case, the data series was divided into two parts (in a 2:1 ratio) for calibration/generation and statistical performance analysis of the estimates (validation), respectively. In this case, an organization was adopted so that the months were contemplated proportionally in the two databases, resulting in 42 and 23 months for generation and validation, uniformly distributed over the years.

The correlations between K_d^h and K_T^h allowed adjustments of third-order polynomials, as recommended by Abreu et al. [29]. Polynomial regression equations were also generated for the K_T^h intervals: $0 \leq K_T^h < 0.55$ (which includes cloudy and partially cloudy sky coverage); and $K_T^h \geq 0.55$ (partly open and open sky), to improve the performance of the estimates. The $K_d^h \times K_T^h$ correlations were generated in total (annual) and seasonal grouping of data.

2.4. Estimates of diffuse radiation by parameterized models

The aforementioned correlations, proposed in this study were compared with 17 parameterized models for estimating hourly diffuse radiation based on the $K_d^h \times K_T^h$ correlation available in the literature for the most different regions of the globe (Table 2). Some of the models are partitioned, with estimation equations for different K_T^h intervals, totaling 42 equations). The table presents the location for which the equations were developed, as well as the corresponding K_T^h intervals. Spencer's [30] equations were adjusted for local latitude.

Table 2. Description of hourly diffuse radiation estimation models used in this study.

Equation number	Authors (reference)	Local	K_T^h ranges	Equations/values
1	Boland et al. [31]	Geelong, Australia (-38.09°; 144.34°)	$0 \leq K_T^h \leq 1$	$K_d^h = 1 / [1 + \exp(7.997(K_T^h - 0.586))]$

42			$K_T^h > 0.75$	$K_d^h = 0.07$

2.5. Statistical performance evaluations of estimation models

In evaluating the performance of the estimation equations and models, the statistical indicators MBE (Mean Bias Error), RMSE (Root Mean Square Error), Willmott's "d" and the coefficient of determination (R^2) (Eqs. 6 to 9, respectively), indicated by Abreu et al. [29] as the most used.

$$MBE = \frac{\sum_{i=1}^n P_i - O_i}{n} \quad (6)$$

$$RMSE = \left[\frac{\sum_{i=1}^n (P_i - O_i)^2}{n} \right]^{0.5} \quad (7)$$

$$d = 1 - \frac{\sum_{i=1}^n (P_i - O_i)^2}{\sum_{i=1}^n (|P_i - \bar{O}| + |O_i - \bar{O}|)^2} \quad (8)$$

$$R^2 = \frac{SQ_{Reg}}{SQ_{TOTAL}} \quad (9)$$

where: P_i – estimated values; O_i – measured values; N – number of observations; $|P_i - \bar{O}|$ – absolute value of the difference $P_i - \bar{O}$; $|O_i - \bar{O}|$ – absolute value of the difference $O_i - \bar{O}$; SQ – sum of squares (obtained from simple linear regression ANOVA).

In evaluating the performance of the estimation equations and models, the statistical indicators MBE (Mean Bias Error), RMSE (Root Mean Square Error), Willmott's "d" and the coefficient of determination (R^2) (Eqs. 06 to 09), indicated by Abreu et al. [29] as the most used.

The MBE and RMSE values represent, respectively, the mean deviation and the actual value of the error produced by the model. Negative MBE values indicate underestimations of the tested model, and vice versa. The smaller the absolute value of MBE, the better the performance of the tested model; the same applies to the RMSE. The concordance index "d" reflects the precision of the estimated values of the observed ones. It takes values between 0 to 1, and the closer to 1, the more perfect the agreement. The determination coefficient measures of how well the model describes the observed data, also the higher the value, the more adequate the proposed model is [42–44].

3. Results

3.1. Radiations and fractions radiometrics

Figure 4 presents the annual diurnal evolution of H_0^h , H_G^h and H_d^h and their respective standard deviations. It is observed that the behavior of global and diffuse radiation is the same as that of incident radiation at the top of the atmosphere, with maximum values at solar noon and minimum values at sunrise and sunset. Mean H_0^h , H_G^h and H_d^h values at 12 hours are 4.57 ± 0.03 ; 2.25 ± 0.12 and 0.53 ± 0.21 MJ m⁻² h⁻¹, respectively. In the hours of rising and setting sun, the average values observed for H_0^h are 0.35 ± 0.07 and 0.41 ± 0.06 MJ m⁻² h⁻¹, and for H_G^h they are 0.04 ± 0.03 and 0.08 ± 0.02 MJ m⁻² h⁻¹; being the global radiation incident at these times practically composed only by the diffuse portion ($H_d^h = 0.03 \pm 0.04$ and 0.06 ± 0.00 at 6 am and 6 pm, respectively).

The photoperiod during the dry and wet/dry transition seasons is shorter due to zenith variations. The seasonal average values of H_G^h and H_d^h , follow the same behavior as H_0^h , with maximums for radiation at the top of the atmosphere during the rainy season (Dec/Jan/Feb) and minimums in the dry season (Jun/Jul/ Aug), both at 12 hours (means of H_0^h : 4.98 ± 0.01 and 4.07 ± 0.00 MJ m⁻² h⁻¹, respectively).

For global radiation, the maximum mean values were observed at solar noon in the dry season 2.47 ± 0.13 MJ m⁻² h⁻¹. A similar behavior is observed by Marques Filho et al. [10] in a study conducted in the city of Rio de Janeiro-RJ (-22.86° ; -43.23°), justified by the fact that the reduction in precipitation in the dry period is related to the decrease in cloud cover, the which raises the levels of H_G^h .

Due to the high cloudiness during the rainy season, the lowest averages of H_G^h and the highest averages of H_d^h (at solar noon) are also observed in this period, 2.02 ± 0.15 and 0.66 ± 0.17 MJ m⁻² h⁻¹, respectively. The minimum averages of H_d^h at solar noon occur in the dry period 0.35 ± 0.04 MJ m⁻² h⁻¹. The lowest standard deviation values for global and diffuse radiation are observed during the dry season, due to the greater stability of atmospheric conditions (Table 3).

Table 3. Diurnal evolution of diffuse radiation (H_d^h) in different seasonal periods, in the region of Sinop-MT, between 2011-2016.

Solar time (hour)	Rainy		Rainy/Dry		Dry		Dry/Rainy

Abbreviation: SD = standard deviation.

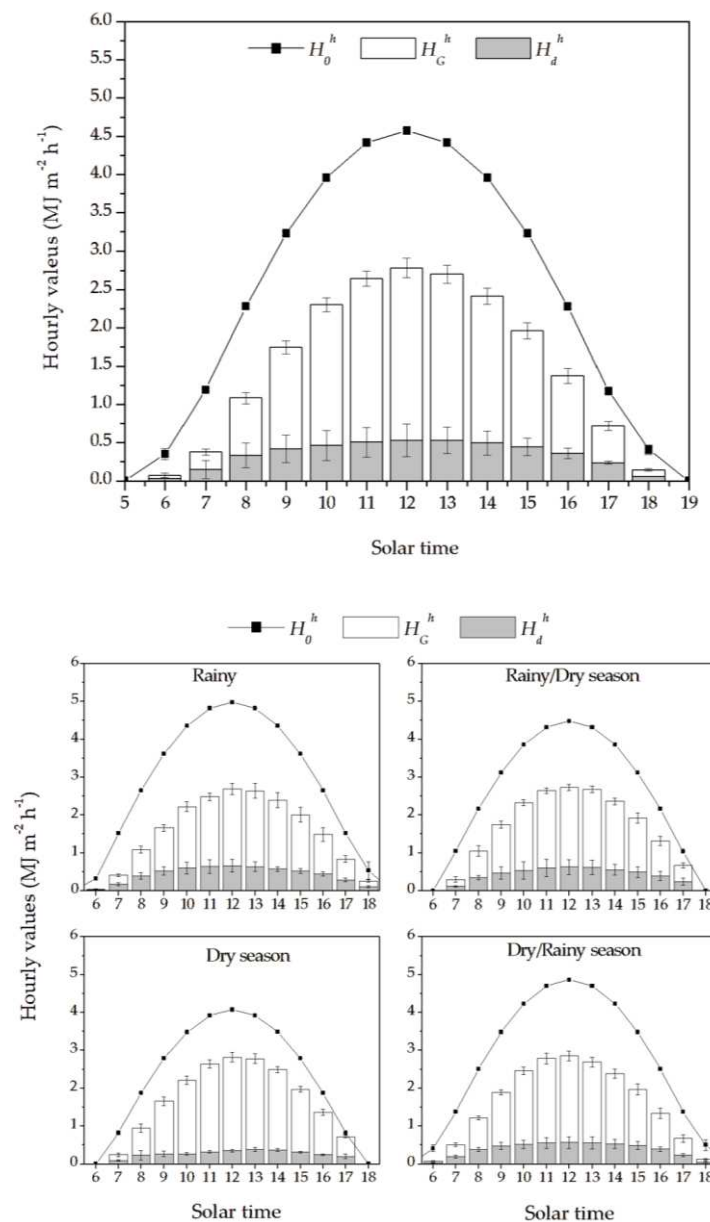

Figure 4. Annual and seasonal diurnal evolution (water stations in the region) of radiation at the top of the atmosphere (H_0^h), global (H_G^h) and diffuse (H_d^h), and respective standard deviations, between 2011-2016, in the region from Sinop-MT.

Figure 5 shows the annual diurnal evolution of the radiometric fractions K_T^h , K_d^h and K_d^h' during the four hydrological seasons. The maximum value of atmospheric transmissivity of global radiation occurs at solar noon, with incident radiation levels on the Earth's surface corresponding to approximately 50% of H_0^h . The minima are observed at sunrise. For a better analysis of atmospheric transmissivity throughout the year.

K_d^h has the opposite behavior to K_T^h , with higher values at the beginning and end of the day. At these times, global radiation is predominantly composed of diffuse radiation, corresponding to about 70% of energy levels (67.66 and 75.22%, respectively). The hourly average values of K_d^h range from 0.15 to 0.78, with a higher hourly average in the rainy season (0.53 ± 0.13) due to the higher concentration of water vapor in the atmosphere. The lower values of standard deviations for K_d^h in the dry season are justified by the greater stability in atmospheric conditions.

The atmospheric transmissivity coefficient K_T^h ranges from 0.07 to 0.64, with a higher average value in the dry season (0.53 ± 0.14) due to low cloud cover, which allows greater passage of direct

radiation. The lowest mean value, consequently, is observed in the rainy season, 0.33 ± 0.11 , while in the transition seasons K_T^h ranges from 0.36 to 0.42.

Through the analysis of the average values of K_T^h , and according to the sky cover classification established by Escobedo et al. [28], it can be stated that the behavior of the sky in Sinop, in the dry season, varies from cloudy to partially cloudy at the beginning of the day, and during the hours it is partially open. In the rainy season, the sky remains cloudy or partially cloudy throughout the day.

In all hydrological stations, the sky is cloudy in the early morning, with a reduction in the atmospheric transmissivity coefficient at the end of the day, except in the dry season, when K_T^h values remain high. Marques Filho et al. [10] state that the high values of K_T^h at the end of the day are due to surface reflections due to the low values of the solar elevation angle at this time of year. Table 4 describes the hourly average values of the components and fractions of solar radiation at 12 noon, in the different hydrological stations.

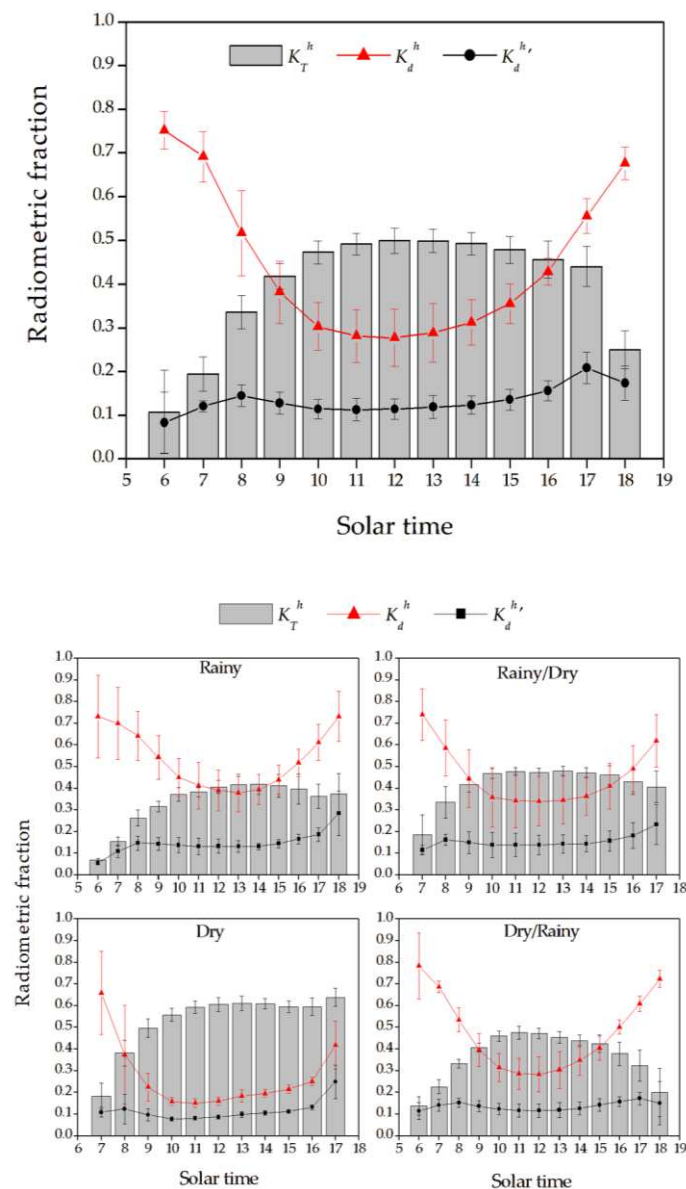

Figure 5. Annual and seasonal diurnal evolution of K_T^h , K_d^h and K_d^h' for the Sinop, MT, Brazil, between 2011 and 2016.

Table 4. Hourly mean values of radiation ($\text{MJ m}^{-2} \text{h}^{-1}$) and radiometric fractions (dimensionless), at solar noon, at different hydrological stations, in Sinop, MT, Brazil, between 2011 and 2016.

Radiation	Rainy	Rany/Dry	Dry	Dry/Rainy
H_0^h	4.98 ± 0.01	4.48 ± 0.01	4.07 ± 0.00	4.86 ± 0.02
H_G^h	2.02 ± 0.15	2.10 ± 0.08	2.47 ± 0.13	2.29 ± 0.13
H_d^h	0.66 ± 0.17	0.63 ± 0.20	0.35 ± 0.04	0.57 ± 0.15
Radiometric fraction	Rainy	Rany/Dry	Dry	Dry/Rainy
K_T^h	0.41 ± 0.03	0.47 ± 0.02	0.61 ± 0.03	0.47 ± 0.03
K_d^h	0.39 ± 0.09	0.34 ± 0.12	0.16 ± 0.02	0.28 ± 0.08
$K_d^{h'}$	0.13 ± 0.03	0.14 ± 0.04	0.09 ± 0.01	0.12 ± 0.03

Zamadei et al. [45] observed the diurnal evolution of K_T^h in the municipality of Juína-MT, 360 km from Sinop-MT, between 10/2007 and 01/2013, and found that the highest values of K_T^h occurred when the Sun had an angle of elevation greater than 45° in relation to the surface, being higher in winter (dry period). As observed in this study, the greatest deviations occurred in the afternoon, indicating an increase in the water vapor content in the atmosphere due to the evapotranspiration process that occurred in the region throughout the day. Also according to these authors, the highest frequencies of clear skies occurred in the months of May, June and July (dry period), while in the period from November to March there was a cloudy sky condition (rainy period), behavior similar to that observed for Sinop-MT.

In Table 5 it is possible to observe the behavior of the sky throughout the year through the frequency of K_T^h within each hydrological station. In the dry season, the condition of partially open sky prevails (31.22%), while in the rest of the year, there is a greater frequency of times with cloudy sky conditions (above 42%).

Table 5. Frequencies of sky conditions (hourly basis) according to the classification by Escobedo et al. [28] in Sinop, MT, Brazil, between 2011 and 2016.

Hydrological period	I (Cloudy)	II (Partially Cloudy)	III (Partially Clear)	IV (Clear)
Rainy	54.90	31.21	9.54	4.35
Rainy/Dry	42.56	31.60	19.63	6.21
Dry	22.53	22.97	31.22	23.28
Dry/Rainy	42.45	39.47	14.92	3.16

3.2. Estimates based on the atmospheric transmissivity coefficient

The $K_d^h \times K_T^h$ correlations are displayed in Figure 6. As observed and described in the literature, with the increase in the clarity index (K_T^h), the diffuse fraction tends to decrease, since there is a decrease in the isotropic effects [46]. Figure 6 shows the behavior of the correlation in the different hydro stations. It is observed that in the dry season the point cloud is more concentrated for K_T^h values greater than 0.4; since in this season sky conditions II, III and IV predominate (Table 6). In the rainy season and rainy/dry transition there is greater data dispersion, indicating that for the same value of K_T^h there is great variability in the values of the diffuse fraction. Borges et al. [23] observed a similar behavior in a study carried out in the State of Rondônia (-10.75° ; -62.35°), attributing this fact to the greater atmospheric variations (cloudiness) that occur during the seasons.

The lowest values of the diffuse fraction when K_T^h tends to 0 can be attributed to the lower horizontal brightness in this region when compared to places at high altitudes and with rugged relief. According to Perez; Seals [47], the horizon zone is infinitesimally thin at 0° elevation.

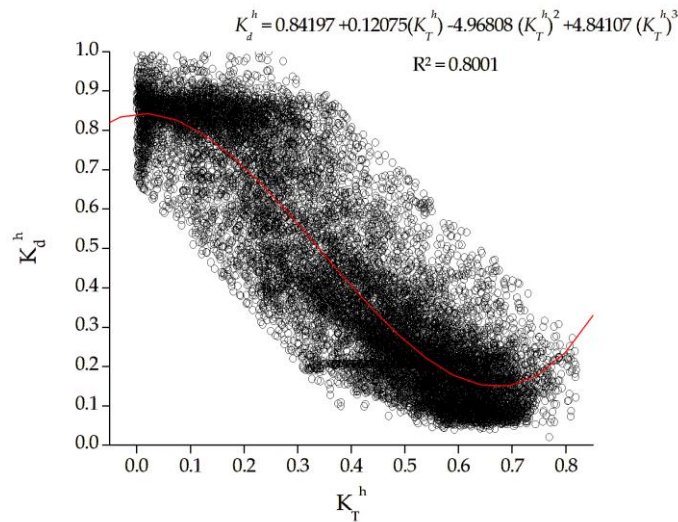

Figure 6. Correlations to estimates K_d^h based on K_T^h , in Sinop, Mato Grosso, Brazil, between 2011 and 2016.

Table 6. Third-degree polynomial regression coefficients and coefficients of determination (R^2), in different datagroups, for estimates of K_d^h based on K_T^h .

K_T^h Interval	Period	Equation	R^2
$0 \leq K_T^h \leq 0.82$	Annual	$K_d^h = 0.84197 + 0.1208 K_T^h - 4.9681 K_T^{h2} + 4.84107 K_T^{h3}$	0.8001
	Dry	$K_d^h = 0.8401 - 0.5850 K_T^h - 3.0117 K_T^{h2} + 3.4476 K_T^{h3}$	0.7927
	Dry/Rainy	$K_d^h = 0.8434 + 0.0107 K_T^h - 4.7464 K_T^{h2} + 4.8705 K_T^{h3}$	0.7790
	Rainy	$K_d^h = 0.8567 + 0.4388 K_T^h - 6.2389 K_T^{h2} + 6.1148 K_T^{h3}$	0.7926
	Rainy/Dry	$K_d^h = 0.8209 + 0.4635 K_T^h - 5.7058 K_T^{h2} + 5.3027 K_T^{h3}$	0.7737
$0 \leq K_T^h < 0.55$	Annual	$K_d^h = 0.8249 + 0.5270 K_T^h - 6.8417 K_T^{h2} + 7.0930 K_T^{h3}$	0.7191
	Dry	$K_d^h = 0.8332 - 0.3581 K_T^h - 4.2099 K_T^{h2} + 5.0256 K_T^{h3}$	0.7097
	Dry/Rainy	$K_d^h = 0.8325 + 0.2254 K_T^h - 5.6085 K_T^{h2} + 5.7841 K_T^{h3}$	0.7338
	Rainy	$K_d^h = 0.8333 + 0.9628 K_T^h - 8.6778 K_T^{h2} + 9.1119 K_T^{h3}$	0.7436
	Rainy/Dry	$K_d^h = 0.8041 + 0.8778 K_T^h - 7.5616 K_T^{h2} + 7.4359 K_T^{h3}$	0.6989
$K_T^h \geq 0.55$	Annual	$K_d^h = 1.7946 - 4.9779 K_T^h + 4.0593 K_T^{h2} - 0.4304 K_T^{h3}$	0.4536
	Dry	$K_d^h = 1.0306 - 1.3726 K_T^h - 1.9669 K_T^{h2} + 3.0059 K_T^{h3}$	0.4302
	Dry/Rainy	$K_d^h = 8.8134 - 39.8605 K_T^h + 61.3930 K_T^{h2} - 31.453 K_T^{h3}$	0.2495
	Rainy	$K_d^h = 3.1103 - 13.0974 K_T^h + 19.7241 K_T^{h2} - 9.9342 K_T^{h3}$	0.0817
	Rainy/Dry	$K_d^h = 2.4911 - 9.7927 K_T^h + 14.2012 K_T^{h2} - 7.0667 K_T^{h3}$	0.3154

The equations generated for the entire K_T^h interval (0 to 0.82) performed better than the sectioned ones, with R^2 above 0.77. In this same interval, the dry and rainy seasons presented better adjustments, which indicates that the atmospheric conditions in the transition periods are more unstable, making estimates difficult. This instability can be explained by the high load of aerosols from biomass burning, an anthropic activity with greater incidence in the months of April and September, corresponding to the periods in question.

The values of the statistical indicators MBE, RMSE and Willmott's d for the estimation equations generated can be observed in Table 7. The seasonal equations, in the intervals of $0.0 \leq K_T^h \leq 0.82$ and $0.0 \leq K_T^h < 0.55$, tended to underestimate the diffuse radiation values during the year. A similar behavior was observed by Oliveira et al. [38] and Borges et al. [23] in the correlations established in

their studies. In the range of $K_T^h \geq 0.55$, there was an inversion of this behavior, with a tendency to overestimates.

Regarding the annual equations, when applied to water stations, there was also a tendency to underestimate the values of H_d^h , especially for $K_T^h \geq 0.55$. The RMSE values ranged from 112.8 to 206.3 $\text{kJ m}^{-2} \text{h}^{-1}$, with higher scattering rates observed in the rainy season, due to the high variation in atmospheric conditions.

The seasonal equations showed better statistical performances when compared to the annual ones in the same periods, except for the rainy season in the intervals $0.0 \leq K_T^h \leq 0.82$ and $0.0 \leq K_T^h < 0.55$, in which the annual equation developed for each partition showed better statistical indicators than the equation for each specific period.

Regarding the annual equations applied to the entire data set, there is a tendency for underestimations in the intervals $0.0 \leq K_T^h \leq 0.82$ and $K_T^h \geq 0.55$, and overestimations of the values when $0.0 \leq K_T^h < 0.55$. Scattering over all K_T^h intervals is about 160 $\text{kJ m}^{-2} \text{h}^{-1}$, and the fit index values are best for intervals $0.0 \leq K_T^h \leq 0.82$ and $0.0 \leq K_T^h < 0.55$.

Table 7. Statistical performance indicators of the hourly diffuse solar radiation estimation equations, generated through the $K_d^h \times K_T^h$ correlation in different datagroups, in Sinop, MT, Brazil.

Abbreviations: MBE = mean bias error ; RMSE = root mean square error; d = Willmott index of agreement.

3.3. Estimates by parameterized models

Table 8 presents the statistical performance indicators of the 42 evaluated equations (17 models) and the 3 equations generated in this study (annual grouping in Table 7). In order to the performance of the tested estimation models, the method of position values (Pv) of the statistical indicators was used, in which weights from 1 to “n” are assigned to each statistical indicator in each model, being “n” corresponds to the number of evaluated equations. In the end, the best model (equation) is the one considered with the lowest accumulated Pv value, obtained by summing the Pv of each equation in each statistical indicative [48]. The models (equations) were classified by the accumulated value of accumulated Pv considering five groups: 1) Pv1 – models with total data grouping ($K_T^h < 0.82$); 2)

Pv2 – all 42 equations; 3) Pv3 – models developed for cloudy sky conditions ($K_T^h < 0.35$); 4) Pv4 – intermediate sky conditions ($0.35 < K_T^h < 0.65$); 5) Pv5 – clear sky conditions ($K_T^h > 0.65$).

The coefficients of determination (R^2) obtained between values measured and estimated by the parameterized equations showed maximum values around 0.70 (some equations did not show significant correlations). Furthermore, these equations generated MBE values ranging from -180.52 to 673.86 $\text{kJ m}^{-2} \text{h}^{-1}$ and scattering (RMSE) ranging from 19.37 to 752.01 $\text{kJ m}^{-2} \text{h}^{-1}$, respectively. The three locally calibrated equations (equations 43 to 45) showed the lowest overestimates of hourly diffuse radiation, regardless of atmospheric transmissivity.

Table 7. Statistical performance indicators of parameterized and calibrated equations in estimating hourly diffuse radiation, in Sinop, MT, Brazil, between 2011 and 2016.

Abbreviations: R^2 = correlation coefficient; MBE = mean bias error ; RMSE = root mean square error; d = Willmott index of agreement; Pv = position values.

For the analysis of models that present sectioned regression equations for different intervals of the atmospheric transmissivity coefficient, those that determine fixed values for K_d^h were disregarded. Subsequently, the statistical performance was analyzed regarding the estimate of diffuse radiation (H_d^h).

For cloudy sky conditions, six equations were analyzed (4, 15, 18, 21, 28 and 31), and the two models generated by Maduekwe; Garba [37] showed the best statistical performances (Table 7 – Pv3 group). These equations despite having low determination coefficients (0.08 and 0.10), these were significant at 5% probability, and when compared with measured values, they showed good results for the agreement index “d” (0.9735 and 0.9592) and low scattering indexes (55.73 and 78.22 kJ m⁻² h⁻¹, respectively). Oliveira et al. [49] states that the coefficient of determination should not be used individually in the analysis of statistical performance, but it can help in decision making when comparing different regression models.

For intermediate sky cover conditions (partly cloudy and partly open) fourteen equations were evaluated, and the best estimates were obtained with the equations generated in this study (Table 7 – group Pv4). The models by Furlan et al. [5], Spencer [30] and Soares et al. [41] adjusted, overestimated the diffuse radiation and presented greater scattering when compared with the results generated by equation 44. As for the open sky conditions (Table 7 – Pv5 group), thirteen models of prediction of diffuse radiation determine fixed values for K_d^h , with the exception of the one generated in this study. Most of these equations tend to underestimate the diffuse fraction, except for equations 14, 20, 23 and 45. For this K_T^h range (above 0.7), the models developed by Erbs et al. [33] Jacovides et al. [34] presented better performances when compared to the others (Pv.5).

Of the ten models that showed the best performance for estimating the diffuse fraction in the different K_T^h ranges, eight were developed or adjusted for tropical regions (latitudes between 6.58° and -23.56°). Of these, five for Brazil, which confirms the influence of this climatic factor on the diffuse radiation incident on the Earth's surface.

4. Discussion

When comparing the annual averages of H_d^h in the morning and afternoon periods, a higher value is observed during the afternoon (0.27 ± 0.21 and 0.33 ± 0.21 MJ m⁻² h⁻¹, for the morning and afternoon periods, respectively). Soil heating, and consequently evapotranspiration, are maximum in the afternoon, which causes greater attenuation of solar radiation due to the high concentration of water vapor present in the atmosphere.

Diffuse radiation behaves similarly to global radiation in hydrological stations, with the exception of the dry season, in which case there is no symmetry between the morning and afternoon periods (Table 3). This behavior may be due to multireflection processes associated with the elevation of the zenith angle, especially in the first hours of sun exposure, with a reduction in the dispersion of suspended particles in the atmosphere.

The increase in the variability of the diffuse fraction of global radiation can also be attributed to a phenomenon called “cloud gap effect” [50–52]. According to the authors, at a given solar elevation angle, a decrease in the atmospheric transmissivity coefficient generally indicates an increase in cloud thickness. However, there is an exception when clouds are not continuously distributed across the sky. Ground surfaces illuminated by the Sun, located at the end of paths of solar beams passing through gaps formed between clouds, may receive greater irradiance than under a clear sky, due to the scattering and reflection of the radiation beam from the side of adjacent clouds. This effect can increase the irradiation incident on the ground by up to 20%. In short, you can increase the K_T^h without indicating that the sky is really open.

If we compare the amplitude of the $K_d^h \times K_T^h$ curve generated in this study (Figure 6) with that of other regions available in the literature, it is possible to notice that the highest number of points for $K_T^h < 0.20$ is concentrated between 0.80 - 0.90 K_d^h , while in other works this value is usually above 0.90. Some authors generate sectioned regression equations, partitioning this K_T^h interval with fixed values for K_d^h [34,35], including in Brazil [5,38,41].

It should be noted that smaller time slices respond more sensitively and quickly to atmospheric changes, generating greater variability and detailing of the punctual distribution of solar radiation, which makes estimation difficult. These effects are minimized when values are integrated into daily and monthly partitions [25,46].

Among the five models (equations 1, 2, 3, 24 and 43) that consider the entire K_T^h interval, the best estimates were obtained by the locally calibrated equation (generated in this study). In this case, the equation proposed by Marques Filho et al. [10] presented the second best accumulated Pv, however, this model was calibrated for the city of Rio de Janeiro (RJ, Brazil), which has atmospheric characteristics distinct from the Cerrado-Amazon transition region, and, therefore, presented overestimates of radiation time difference of up to 323.39 kJ m⁻² h⁻¹. It is interesting to mention that these same authors also evaluated some models evaluated in the present study [26,32,34] to estimate the local diffuse radiation, however, observed better statistical performances when using the locally developed correlation model.

Singh [53] compared the efficiency of diffuse radiation estimation models considering the entire range of the atmospheric transmissivity coefficient and intervals of cloudiness classes, and concluded that, in general, the models present similar statistical performances for regions with well-defined water seasonality (rainy and dry seasons). These observations by Singh [53] corroborate those found in the present study, through the analysis of the statistical performance of the 45 equations (group Pv2), since the five aforementioned (which consider the entire K_T^h value) were classified as 14th, 30th, 34th, 38th and 40th, respectively. In this case, the equations that estimate K_d^h in intermediate sky cover performed better than the others of the same model.

The diffuse radiation database obtained in the region of Sinop, MT (Brazil) can be considered short (5 years), however, it allows applications directed mainly towards the calibration of models of estimates of diffuse radiation. The studies focused on the analysis of seasonality and estimates on daily integration have already been presented by Zamadei et al. [19,20]. The network of stations of the National Institute of Meteorology (INMET) routinely monitors hourly global horizontal radiation,

and, with good estimates of diffuse radiation, it is possible, by difference, to obtain information on direct radiation in horizontal planes.

It is recommended for future works the modeling of estimation equations with the insertion of a larger number of meteorological variables, to verify the performance in relation to the models generated in this study, as well as the evaluation of those existing in the literature. The correlation between the diffuse fraction and the insolation ratio can also be worked on, in order to propose models with an easily obtainable variable.

It should also be noted that there is an urgent need to implement a network of solarimetric stations in the Cerrado and Amazon regions, considered important Brazilian biomes. There are no scientific reports of any radiometry monitoring in the aforementioned regions. This type of monitoring is essential to guide environmental and engineering studies in the most varied areas of knowledge. These stations must, above all, routinely monitor at intervals of 5 or 10 minutes, in horizontal planes, the spectral components of solar radiation (ultraviolet, visible and infrared) and diffuse, direct radiation and reflected radiation.

5. Conclusions

The hourly diffuse radiation in the region of Sinop-MT presents similar behavior to the incident radiation at the top of the atmosphere and globally, with maximum values at the lowest zenith angles. Seasonality indicates higher hourly diffuse radiation levels K_d^h in the rainy season in the region.

The radiometric fractions also show characteristic behavior during the different water seasons. The highest values of the atmospheric transmissivity coefficient K_T^h were observed in the dry season due to low cloud cover.

The $K_d^h \times K_T^h$ correlation established showed a peculiar behavior, with the amplitude of the curve characteristic of regions located at low latitudes (closer to the Equator). As in other studies, when K_T^h tends to 0.0, K_d^h tends to 1.0; however, for K_T^h values lower than 0.20, the maximum observed K_d^h values ranged from 0.80 to 0.90.

Polynomial equations were generated to estimate the diffuse radiation considering three intervals of K_T^h , and these equations presented better statistical performances when compared with parameterized equations from the literature.

Among the 17 models (42 equations) for estimating the parameterized diffuse radiation evaluated, it is recommended to use the polynomials developed in this study or the one elaborated by Marques Filho et al. (2016) for estimates of the K_d^h fraction, in the range of $0.0 \leq K_T^h \leq 1.0$, for regions climatically similar to the Cerrado-Amazon transition of Mato Grosso.
