**Abstract:** Familial Exudative Vitreoretinopathy (FEVR), Norrie disease, and persistent fetal vascular syndrome (PFVS) are extremely rare retinopathies that are clinically distinct but are unified by abnormal retinal endothelial cell function – and subsequent irregular retinal vascular development and/or aberrant inner blood-retinal-barrier (iBRB) function. The early angiogenesis of the retina and its iBRB is a delicate process that is mediated by the canonical Norrin Wnt-signaling pathway in retinal endothelial cells. Pathogenic variants in genes that play key roles within this pathway such as *NDP*, *FZD4*, *TSPAN12*, and *LRP5*, have been associated with the incidence of these retinal diseases. Recent efforts to further elucidate the etiology of these conditions have not only highlighted their multigenic nature but have also resulted in the discovery of pathological variants in additional genes such as *CTNNA1*, *KIF11*, and *ZNF408*, some of which operate outside of the Norrin Wnt-signaling pathway. The goals of this review are to briefly highlight the current understanding of the roles of their encoded proteins in retinal endothelial cells to understand the essential functional mechanisms that can be altered to cause these very rare pediatric retinal vascular diseases.

## 1. Introduction

The retinal endothelial cell (REC) plays a central role in the developmental formation of the mammalian neural-retinal vasculature [1]. A retinal specific growth factor Norrin is essential for stimulating the proliferation of the retinal vasculature and recruitment of mural cells [2]. Genetic variants that change normal REC function can potentially impact the development of the entire neural retina and its function. At maturity, three interconnected microvascular beds support the inner neural retina: the Superficial Plexus in the Ganglion Cell Layer (GCL) / Nerve Fiber Layer interface, the Intermediate Plexus on the inner-side of the Inner Nuclear Layer (INL), and the Deep Plexus on the outer-side of the INL. See Figure 1. We recommend the review by Selvam et al., for those interested in the topic of retinal vascular development [3].

**Figure 1. Location of the inner-Blood-Retinal-Barrier (iBRB) and retinal endothelial cells.** The neural retina is comprised of several distinct layers. The red tracts indicate the location of the three vascular beds of the iBRB. The relative temporal order of their formation during development are shown by numbers. In the orientation of this diagram light enters from the top and passes through the retinal layers to reach rod and cone opsins in the outer segments (OS) of photoreceptors. Photoreceptor nuclei are packed closely in the Outer Nuclear Layer (ONL). Photoreceptor cells form synaptic connections with downstream inter-neurons in the Outer Plexiform Layer (OPL). Nuclei of Bipolar Cells, Horizontal Cells and some Amacrine Cells comprise the Inner Nuclear Layer (INL). In the Inner Plexiform Layer, the Bipolar and Amacrine Cells form synaptic contacts with Ganglion Cells in the Ganglion Cell Layer (GCL). An Inner-Limiting Membrane (ILM) lays on top of the retina and the superficial plexus. Retinal Pigment Epithelium (RPE).

Inner-retinal neurons (Bipolar Cells, Horizontal Cells, Amacrine Cells and Ganglion Cells) are fully dependent on this inner-retinal vasculature for gas, nutrient and waste exchange. Photoreceptors are less reliant on this vasculature and are supplied by the Choroidal Blood supply which is located on the opposite side of the Retinal Pigment Epithelium (RPE). This fact is well demonstrated by the mouse Oxygen-Induced Retinopathy model where inner-retinal neurons are lost during post-natal retinal development in zones that become avascular for several days before neovascular growth restores the blood supply. OCT and ERG analysis show that even with severe inner retinal neuron loss, the photoreceptors are not lost in any substantial numbers, and photoreceptors remain responsive to light [4–6].

During normal retinal development, the superficial layer extends first from the optic nerve towards the peripheral retina, resulting from proliferation of advancing retinal endothelial cells [1]. Vertical branch sprouts form from this layer and follow guidance cues from Muller Glia Cells which extend from the ILM to the outer side of the ONL. The deep plexus then extends horizontally ahead of the intermediate plexus, which forms last. Active proliferation of RECs is essential for the formation of this vasculature and after maturation RECs are essential components of the neurovascular unit that supports formation of the inner blood-retinal-barrier (iBRB) and its high-barrier nature. The iBRB is a highly selective barrier like the Blood-Brain-Barrier (BBB) and indeed the neural retina is part of the Central Nervous System (CNS).

The high-barrier nature of the retinal endothelium is a result of specific adaptations to decrease the permeability of the endothelium both between and through the cells. A relatively high-barrier to paracellular transport, between cells, is provided by high concentrations of adherens- and tight-junctions between neighboring cells [7]. Reduced concentration of plasmalemma vesicles, which are caveolae vesicles associated with Caveolin protein, is responsible for a lower rate of transcytosis, transport through retinal endothelial cells [8]. Unlike choroidal endothelial cells, retinal endothelial cells are not fenestrated. The iBRB is compromised in certain pathological eye diseases such as diabetic retinopathy, which manifests clinically as increased microvascular permeability and subsequent retinal hemorrhages [9]. Increased concentration of Vascular Endothelial Growth Factor-A is a major driver of barrier loss from disruption of the adherens-junctions and tight-junctions. VEGFA was also shown to increase the concentration of caveolae in bovine RECs [10].

While RECs are clearly integral to sustaining retinal vascular structure, they are also key players in the development of the early retinal blood supply. Norrie disease, Coats disease, retinopathy of

prematurity (ROP) and familial exudative vitreoretinopathy (FEVR) belong to a family of rare retinopathies that are characterized by irregular vascularization or even lack of vascularization of the retina [11]. Our group has contributed to continuing efforts to identify variants in several genes that play a role in the pathogenesis of these diseases, which include *NDP*, *FZD4*, *TSPAN12*, and *LRP5*, members of the canonical Norrin Wnt-signaling pathway [12]. Recent studies have also uncovered additional genes, some that have no direct participation in the Norrin-signaling pathway. They include *CTNNB1*, which encodes the canonical Wnt-signaling transcription factor  $\beta$ -Catenin [13]; *KIF11*, which codes for kinesin-motor protein-11, KIF11, active during mitosis [14]; and *ZNF408*, which encodes a zinc-finger rich transcription factor (ZNF408) that has heightened expression in the developing eye [15].

Despite their distinctively unique cellular roles, these genes all share the following characteristic: variants in their coding sequence will negatively impact essential functions of the retinal endothelial cell and can lead to aberrations in retinal vasculogenesis and/or maintenance of inner BRB integrity. Furthermore, the degree to which they are limited to their specific impact on the neural retinal endothelium, versus multi-syndromic pathologies, tends to reflect the relative specificity of their expression in retinal endothelial cells. This review will provide a brief overview of each of these genes, including the general structure and function of their respective proteins, and their impact on retinal endothelial cell function in the developing retina.

2. Genes and Proteins

For each gene we have included a figure that maps the location of many known pathogenic and likely-pathogenic variants relative to known functional protein domains. Please note that many known variants of *uncertain consequence* were not included in the figures, but the reader can also view them in the UniProt database (<https://www.uniprot.org>) or other databases with variant information. The reader should also keep in mind that this variant information is not static and reference to online databases is recommended in addition to searches of the recent literature. Below we review seven FEVR-linked genes, beginning with those linked more recently to FEVR, followed by those with direct roles in Norrin Wnt-signaling: *KIF11*, *ZNF408*, *CTNNB1*, *NDP*, *FZD4*, *LRP5*, and *TSPAN12*.

2.1. KIF11

KIF11 is located on Chr-10 that encodes for Kinesin Family member-11 (also known as Eg5) a homo-tetrameric motor protein that is involved in the formation of spindle polarity during mitosis [16]. KIF-11 consists of three major functional components: an N-terminal motor domain, two coiled-coil domains, and a cargo protein interaction domain at the C-terminal end. A structural map of KIF-11 and the locations of most known pathogenic and likely-pathogenic protein-altering variants is shown in Figure 2.

**Figure 2. Structure and functional domain map of the KIF-11 protein.** Key features of the KIF-11 amino acid sequence include an ATP-binding motor-domain region, coiled-coil domains for multimer

formation, and a C-terminal domain for cargo-protein interactions. Over 30 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. FEVR and non-FEVR disease variants are shown. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/P52732>.

Structurally, Kinesin Motor family proteins form dimers or tetramers with the coiled-coiled domains of each monomer entwined with the equivalent domains of their multimeric partners. This elongated structure also serves as a long connecting towbar between the motor-domain region and the cargo binding domain. As such, most of the protein's amino acid sequence is important for movement of KIF11 along microtubules, correct multimeric formations, and for the tethering of any required cargo.

Heterozygous variants in this gene have been linked to microcephaly with or without chorioretinopathy, lymphoedema, or mental retardation (MCLMR), a rare autosomal dominant disease [17,18]. However, a recent study by Li et al., have discovered an association with KIF11 variants and the development of familial exudative vitreoretinopathy [14]. Variants included L171V, Q525\*, S936\*, and R1025G [14]. The data suggested that there was a trend between mutations in KIF11 and more severe phenotypic outcomes of FEVR – all probands in one study with KIF11 variants were diagnosed with either stage 4 or 5 FEVR.

Generally, disease-causing KIF11 variants result in multiple syndromic conditions in addition to impacting development of the retinal vasculature. This is congruent with the fact that KIF11 appears to be involved in the process of spindle formation and organization during cell division, a fundamental cellular process not limited to the retinal endothelial cell. It is presumed that the major impact of these disease-causing variants is mostly impacting the normal proliferation and migration of RECs in the developing neural retinal vasculature. Early-post natal, endothelial cell specific, knock-out of KIF11 in the mouse was reported to impair the formation of the retinal and cerebellar vasculature [19]. The capacity of EC cells for  $\beta$ -catenin mediated intracellular signal transduction was not impacted. Wang and co-authors have hypothesized that the cerebral and retinal microvasculature may be more sensitive because these vascular beds are the most rapidly growing later in embryonic development.

2.2. ZNF408

ZNF408 is located on Chr-11 and encodes a protein consisting of one PR-SET domain and 10 zinc (Zn)-finger domains. See Figure 3. This protein belongs to the PRDM family (PRDI-BF1 and RIZ homology domain containing) of transcription factors, which are characterized by the presence of a PR domain followed by a variable number of Zn-finger repeats [20].

**Figure 3. Structure and functional domain map of the ZNF-408 protein.** Key features of include an PR-SET domain and 10 zinc-finger domains. Several pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid

code. FEVR and non-FEVR disease variants are shown. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/Q9H9D4>.

The PR-SET domain is involved in the recruitment of chromatin remodeling factors such as those modulating DNA-methylation. Multiple Zn-finger motifs occurring in close sequence are known to provide specific structures for binding interactions with other proteins or for binding to specific DNA-sequences. Members of this protein family can act as transcription factors, regulating a diverse range of function-related gene expression and some aspects of DNA repair [21].

Changes to the coding sequence of Zn-finger proteins have been associated with aberrations in tissue development, cancer, retinitis pigmentosa, and recent genetic studies have identified several variants associated with FEVR [15,22]. For example, the H455Y variant was identified in a family with autosomal-dominant FEVR [23].

Studies in zebrafish have confirmed that some of these variants resulted in irregular retinal vasculature development, while studies using human umbilical vascular endothelial cells (HUVECs) revealed that variants in ZNF408 reduced endothelial cell capacity for angiogenesis [15,23]. While further research is required to identify the specific gene expression changes associated with variants of ZNF408, one hypothesis suggests that variants in ZNF408 results in the decreased transcription of genes responsible for the formation of new capillaries in response to hypoxia[23].

2.3. CTNNB1

Located on Chr-3, CTNNB1 encodes the protein  $\beta$ -catenin. Before  $\beta$ -catenin variants were reported for FEVR, many variants of this gene were already associated with cancers. The roles of  $\beta$ -catenin can be relatively complex because of its regulatory roles in cell-to-cell adhesion and its pivotal role in canonical Wnt-signaling. Many cancer-related variants are clustered in the N-terminal domain of  $\beta$ -catenin where they prevent the normal regulatory targeting of the protein to degradation at the proteasome. See Figure 4. This effectively results in abnormally constant hyperactivity of  $\beta$ -catenin, which promotes cancer-cell proliferation [24]. In addition to its central role in Wnt-signaling, most  $\beta$ -Catenin is associated with E-Cadherin of the adherens-junctions in endothelial cells [25].

**Figure 4. Structure and functional domain map of the  $\beta$ -Catenin protein.** Key features include 12 imperfect ARM repeats, flanked by the N-terminal and C-terminal domains. The protein has numerous regulatory protein interaction partners that bind beta-catenin in separate domains but also in some overlapping regions. The N-terminus is essential for binding with alpha-Catenin as well as the beta-TrCP ubiquitin ligase that targets  $\beta$ -catenin for proteasome degradation. Over 100 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. FEVR and non-FEVR disease variants are shown. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A

current view of variants was obtained from the UniProt data base:  
<https://www.uniprot.org/uniprotkb/P35222>.

Most of the protein's amino acid sequence comprises 12 ARM motifs, with each ARM region forming an alpha-helical structure. These multiple helixes are stacked together laterally, like logs, with this entire log-stack also twisted into a higher-order helical structure. Most of the length of this large super-structure forms a groove that provides for interactions with proteins such as TCF/LEF transcription factors[26]. For an excellent and detailed review of  $\beta$ -catenin's structures we refer the reader to Huber and Weis (2001). While most variants in CTNNB1 are cancer-promoting and located near the N-terminus, studies have reported FEVR- and PFVS-linked variants. Two such examples are a frame-shift-causing five base-pair insertion and the A295G variant in probands with FEVR and PFVS, respectively [13,27].

#### 2.4. NDP

NDP (Norrie Disease Protein, Norrin) is a cysteine-rich protein that serves as the ligand for the Norrin Wnt-signaling pathway. Norrin has been found to function as an angiogenic factor and as a neuroprotective growth factor [28]. Norrin mediates angiogenesis partly through the induction of insulin-like growth factor-1 [29]. The *NDP* gene is located on Chr-X and subsequently, symptomatic probands are more often male. While associated with Norrie Disease, missense variants in NDP are also associated with diagnosed FEVR, both X-linked and sporadic [30]. Pathologic variants in NDP have been associated with several vascular retinopathies, including Norrie disease, FEVR, persistent fetal vasculature syndrome (PFVS), retinopathy of prematurity (ROP), and Coats disease [11]. While these retinopathies are largely limited to the retinal vasculature, Norrie disease exhibits the most severe manifestations with retinal dysgenesis and is unique in its association with several additional symptoms, including intellectual disability, seizures, alterations to peripheral vascular structure, and gradual hearing loss [11].

The Norrin protein is secreted by Müller cells and the Norrin homodimer binds to FZD-4, which triggers canonical Wnt-signaling that governs angiogenesis in the retina and the inner ear [31,32]. TSPAN-12 and LRP-5 are co-receptors that enhance this binding. See Figure 5. Studies have identified the specific interacting regions between Norrin and FZD-4 or LRP-5 and confirmed that variants altering these structures result in decreased signaling activity via this essential pathway [31].

**Figure 5. The Norrin-Wnt signaling pathway in retinal endothelial cells.** The main functional proteins in the Norrin Wnt-signaling pathway, which is active in neural retinal endothelial cells.

Norrin's binding affinity for FZD-4 is increased when the co-receptors Tspan-12 and LRP-5 are present. Direct protein-protein interactions are indicated between various partners in the complex by dashed double-arrows. Specific extracellular domains and surfaces of proteins within this ligand/receptor complex provide the various interactions and the synergy which makes retinal endothelial cells uniquely sensitive to Norrin. Activation of the pathway by Norrin binding blocks the inactivation of the Destruction Complex, which reduces the delivery of  $\beta$ -catenin to proteosome-degradation. Elevation of cytoplasmic beta-catenin and its translocation into the nucleus lead to interaction with LEF/TCF transcription factor family to regulate the expression of target genes. General structural domains and features are illustrated for Norrin, FZD-4, LRP-5, Tspan-12, including transmembrane domains, extracellular loops and other extracellular domains that are involved in protein interactions.

Structurally, NDP consists of two main domains: an N-terminal signal peptide which is involved in facilitating the protein's extracellular export and a highly conserved cysteine-knot motif, which makes up the bulk of the protein. See Figure 6.

**Figure 6. Structure and functional domain map of NDP (Norrin).** Key features include an N-terminal signal peptide required to target Norrin for extracellular transport. Four longer and four shorter beta-strand regions are layered in the Norrin monomer and the entire tertiary structure is stabilized by multiple disulfide bridges. The so-called cysteine knot domain involves most of the mature Norrin amino acid sequence. Over 50 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/Q00604>.

Protein variants that alter the cysteine-knot confirmation are associated with more detrimental outcomes involving dysplasia or dysgenesis of the retina (i.e. Norrie disease) while variants that are located outside the motif are more commonly seen in patients with FEVR, in which the retina is present, albeit incompletely vascularized [33]. FEVR-associated genetic changes include R121Q, which has been identified by multiple studies across ethnically diverse populations, and S57X and K104Q, which have been present in cases of both FEVR and Norrie disease [34]. This highlights the interconnectedness of the mechanisms that underlie these two conditions.

This signaling pathway is specific to the retinal endothelial cell by virtue of the unique combination available of all four members of the ligand/receptor complex in the retinal endothelial cell: Norrin, FZD4, LRP5 and TSPAN12. Genetic loss of function experiments in mice indicate that while there is some overlap of Norrin and Wnt7a/Wnt7b signaling systems in the retina and brain, Norrin is more important for the iBRB and Wnt7a/7b has the larger role in development of the Blood-Brain-Barrier [35]. Subsequently, changes to the structure of any of these four proteins have been linked to similar retinal vascular pathology, such as FEVR or ROP [36]. Interestingly, while FEVR's

presentation can differ greatly across individuals, studies in mice have indicated that loss of function in Norrin, FZD-4, or LRP5 can often result in similar clinical phenotypes [36]. Ohlmann et al., demonstrated that ectopic expression of Norrin restored normal retinal angiogenesis that is lost in *Ndp* knockout mice [37].

Because of Norrin’s central role in the development of the iBRB and its involvement in the pathogenesis of various retinopathies, recent research has been centered on Norrin’s capacity to combat the effects of VEGF-induced capillary leakage. Using a diabetic retinopathy mouse model, these studies indicate that exogenous Norrin can help to restore the retinal endothelial cell junctions via the canonical Norrin Wnt-signaling pathway [38]. Our research group has demonstrated that a single intra-vitreous injection of Norrin protein can accelerate vascular regrowth and reduce inner-retina neuronal cell loss in the mouse oxygen-induced retinopathy model [6,39].

2.5. FZD4

As has been highlighted in this paper, the Wnt-signaling pathway is responsible for the maintenance of the blood-retina-barrier in the eye as well as for governing the process of retinal angiogenesis in the developing retina. The *FZD4* gene on Chr-11 encodes Frizzled Class-4 Receptor, a member of the Frizzled gene family which are also 7-transmembrane domain proteins. FZD-4 is the central cognate receptor for binding Norrin and is required for retinal angiogenesis and formation of the iBRB [40,41]. Norrin’s binds to FZD-4 and co-receptors LRP5 and TSPAN12, and subsequently, changes to the structure of any of these four proteins can cause retinal vascular pathology, such as FEVR or ROP [36]. Interestingly, while FEVR’s presentation can differ greatly across individuals, studies in mice have indicated that loss of function in Norrin, FZD-4, or LRP5 can often result in similar clinical phenotypes [36].

*FZD4* is located on chromosome-11 and the protein it encodes is made up of 7 helix domains, a PDZ-binding domain, and a cysteine-rich binding domain located near the N-terminus that is presented extracellularly and serves as the NDP binding site. See Figure 7. NDP is not known to bind to any other members of the Frizzled family of receptors, which highlights the specificity of the NDP/FZD-4 ligand/receptor relationship [36].

**Figure 7. Structure and functional domain map of FZD-4 (Frizzled-4).** Key features include an N-terminal Wnt-binding domain, seven transmembrane helical regions, and a PDZ-binding domain. 25 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/Q9ULV1>.

Some examples of single missense variations of *FZD4* that are linked to FEVR include M105V, R417Q and G488D [42]. A sequencing survey of subjects with FEVR, Norrie Disease, PRVS, Coats Disease and ROP found a strong statistical association of a double variant, p.[P33S(;)P168S], with ROP itself and a moderate statistical association with infant birth weight [43]. The locations of 25 pathogenic and likely-pathogenic variants are shown in Figure 7. We expect that the sequencing of new FEVR subjects will continue to reveal novel pathogenic variants. One such recent example was reported by our group recently, Cys450Ter, a nonsense that generates an early termination codon

within TM helix-6. This was predicted to result in the loss of TM helix-7 and the C-terminal PDZ-binding domain of the FZD4 protein [44].

2.6. LRP5

The LDL-Receptor-Related Protein-5 is encoded by the *LRP5* gene on Chr-11 and is expressed in retinal endothelial cells. We refer the reader to He et al., for a more detailed review regarding the LRP-5 and LRP-6 receptors [45]. As noted above, in conjunction with TSPAN-12, LRP-5 acts as a co-receptor that enhances Norrin’s binding affinity for FZD4. LRP5 is required for vascular development in the deep plexus of the neural retina [46,47]. LRP-5 protein has four extracellular Beta-Propeller / EGF-Like domain regions, one transmembrane domain region, and two intracellular disordered domains at the C-terminus. See Figure 8.

**Figure 8. Structure and functional domain map of LRP-5.** Key features include the transmembrane domain, two intracellular disordered domains and four extracellular Beta-Propeller / EGF-Like domain regions . Over 90 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. FEVR and non-FEVR disease variants are shown. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/O75197>.

LRP-5 has direct interactions with Norrin, using positively and negatively charged amino-acid sidechains. (See Figure 5). The Beta-Propellor domains -1 and -2 nearer the extracellular N-terminus, interact with the edge of the Norrin dimer, away from where FZD4 interacts with the central surface of the Norrin dimer. A ternary complex is formed once LRP-5 and FZD-4 are bound to Norrin [31].

In addition to FEVR, pathologic mutations in LRP-5 are also associated with familial osteoporosis and high bone density syndromes [48]. Studies have identified several mutations in *LRP5* associated with FEVR. They include L145F, R444C, A522T, T798A, and N1121D [49]. Qin et al., noted that these five missense mutations fall within the highly conserved beta-propeller domains of the LRP-5 protein [49].

2.7. TSPAN-12

TSPAN-12 is a member of the tetra-spannin protein family, which are characterized by four transmembrane domains with both their C-terminus and N-terminus being in the cytoplasm. These 4-transmembrane domains are linked by one small extracellular loop, one small intracellular loop, and one large extracellular loop. Interactions with other proteins and the variable roles of different tetra-spannin proteins are strongly impacted by amino acid sequence differences in the large extracellular loop [50]. See Figure 9.

**Figure 9.** Structure and functional domain map of TSPAN-12. Key features include the four transmembrane (TM) helical domains, the large extracellular loop region, and the dimer interface region. TSPAN-12 is a member of the tetra-spannin family of membrane proteins. Both the N-terminal and C-terminal domains are intracellular. 13 pathogenic and likely-pathogenic variants are indicated by red circles with the variant amino acid indicated by the standard single-letter amino acid code. The bottom row \* indicates the location of nonsense (stop codon) variants that truncate the protein. A current view of variants was obtained from the UniProt data base: <https://www.uniprot.org/uniprotkb/O95859>.

*TSPAN12* variants can cause autosomal dominant FEVR [51]. Variants of human TSPAN-12 have also been linked with ROP, specific types of cancer via regulation of progression, viral infections using TSPAN-12, and mental retardation [52–54]. Many variants identified in probands diagnosed with FEVR are predicted to result in a truncated protein, though studies were unable to perceive a difference in clinical presentation between patients with shortened proteins and those with missense mutations [51]. A237P is a variant observed in at least five families with FEVR [55].

Elegant work by Junge et al., used transgenic and knockout combinations in mice to demonstrate that normal vascularization of the neural retina required a full combination of *Fzd-4*, *Lrp-5*, and *Tspan-12*, as well as *Norrin* [56]. Loss of one allele of *Tspan-12* or *Lrp5* caused minimal reduction in vertical sprouts in the neural retina. Losing one allele each of *Tspan-12* and *Lrp5* had a much greater effect on this reduction. Complete lack of the *Tspan12* protein in homozygous knockouts resulted in the failure to form vertical sprouts from the superficial plexus of the developing retinal vasculature. Furthermore, in cell-based transfection assays, TSPAN-12's ability to enhance *Norrin*/beta-catenin signaling relied on the co-transfection of both *FZD4*, *LRP5*.

Additional studies with *Tspan-12*<sup>(-/-)</sup> mice confirmed a significant increase in large retinal vessels and abnormal arterial-venous crossing along with upregulation of VE-Cadherin, which regulates iBRB integrity and EC inactivity (Zhang et al. 2018). These retinas also displayed a lack of intraretinal capillaries, and glomeruloid vessel malformations, which were like defects observed in pathogenic variants of *Ndp*, *Fzd4*, and *Lrp5* (Zhang et al. 2018). Mural cells were also reduced or absent in some areas of the retinas of *Tspan-12*<sup>(-/-)</sup> mice. Additional features included microaneurysms, impaired hyaloid vessel regression, focal hemorrhages, retinal glial cell activation, and upregulation of plasmalemma vesicle-associated protein (PLVAP). The later effect was presumably due to impairment of *Norrin* signaling, as *Norrin*-Wnt signaling is one factor thought to suppress PLVAP expression in retinal endothelial cells, which is essential to generate its high-barrier nature.

### 3. Conclusions

We can draw several conclusions from this brief review regarding the mechanisms underlying FEVR.

1. As we survey the protein domain maps that we have presented of currently known pathogenic and likely-pathogenic variants; we can conclude that almost any functional subdomain of these proteins can be involved. This is not surprising as studies of these proteins have established important protein-interaction functions or structural functions that are essential for their normal biological activity. Generally, there are little if any non-essential regions in the seven proteins reviewed.
2. FEVR can involve the disruption of any one of several different functions in endothelial cells, not just those related directly to the Norrin Wnt-signaling pathway. This is established by disease-causing variants in ZNF408 and KIF11. However, what all these genes and their protein products have in common is that they are particularly important for critical retinal endothelial cell activity. These include growth, proliferation, and migration of endothelial cells during formation of the retinal vasculature and maturation of a high-barrier endothelium. It is possible, and expected, that we may continue to discover novel FEVR-linked genes and good candidates would be any gene that is particularly enriched in retinal endothelial cells versus other endothelial cells, and genes with the potential to impact EC proliferation or the maturation of their high-barrier character.
3. The multiple allele knockout studies by Junge et al., (2009) in mice suggested the possibility that more severe FEVR-like phenotypes could result from combinations of two or more different alleles that have a minimal impact alone [56]. Our group recently surveyed a cohort of FEVR patients and immediate relatives to confirm that the incidence of protein-altering variants in two or three different FEVR-linked genes was substantially greater than in the general population [12]. Thus, it is possible that combined mild-alleles might result in more severe phenotypes, but we have not yet described clear examples of this in FEVR. To explore such possibilities for this relatively rare condition it will be helpful to apply genetic testing methods that survey as many genes as possible and to form global research collaborations to investigate genotypes and phenotypes from varied populations.

Rare inherited retinal vascular diseases such as FEVR, Norrie disease, and Persistent Fetal Vascular Syndrome have historically been difficult to study due to their scarcity in the population, their complex presentations, and subsequently, their challenging diagnosis. Moreover, these conditions are sometimes multigenic and it is possible that the severity of phenotypes may be impacted by combinations of two or more protein-altering variants that may have no phenotype, or a mild phenotype, on their own. Clear evidence of such multigenic contributions is yet to be described and deserves the attention of future investigations. While this highlights the challenges of genetic testing for patients with rare retinal pathology, it is imperative that efforts continue to elucidate the mechanisms that govern these conditions.

**Author Contributions:** “Conceptualization, K.K. and V.L.; writing—original draft preparation, V.L, K.M., G.A., C.P., V.J., and R.R. ; review and editing, V.L, K.M., W.D., and K.D. ; visualization, K.M. and G.A.; supervision, K.M.; funding acquisition, K.M. All authors have read and agreed to the published version of the manuscript.”.

**Funding:** Authors who worked on this review were supported in part by the Pediatric Retinal Research Foundation, Michigan, USA and the Carls Foundation, Michigan, USA.

**Institutional Review Board Statement:** Not applicable. Topic review only.

**Conflicts of Interest:** “The authors declare no conflict of interest.”.
