**Abstract:** The authors of the article analyze the existing methods and models of technological preparation of machine-building industries. The structure of a three-level simulation model with network-centric control, the structures of individual elements of the simulation model and the process of simulation modeling are described. The criteria for choosing a rational option for the processing technological route have been determined. During the research, a simulation program was implemented in C++. It allows you to select the optimal scenario for the operation of a production site based on two criteria: time and cost. The volume of implementation is about  $2 \times 10^3$  lines of code. A diagram of the modeling algorithm for the implemented program, a description of the classes and their interactions are given in the article. The developed simulation model was tested at a machine-building enterprise using the example of the "Pusher" part, manufactured under single-unit production conditions. The technological equipment used for the manufacture of this part was formed in the form of input data of the simulation model. The results of simulation modeling for the selected part are described. For each variant of the technological processing route, the values of variable costs and the duration of the production cycle were determined.

**Keywords:** technological preparation of production; automation of production processes; small-scale production; single production; machine-building enterprises

## 1. Introduction

The current direction of organizing modern production is the transition to advanced digital, intelligent production technologies and robotic systems. Within this direction, the defining trend of the future material production of goods and services is the use of production networks with network-centric control [1]. Examples of modern production sites are complexes of multifunctional computer numerical control (CNC) machines, 3D printers and robots, which are integrated into a network to create conditions for effective planning and optimal implementation of parallel technological processes [2-5]. A feature of technological processes is their adaptability to small-scale or piece production in such areas as mechanical engineering, processing of raw materials, assembly of multi-component products, etc. [6,7]

Technological preparation of production (hereinafter referred to as TPP) is one of the most important stages of the process for the production of parts. The Chamber of Commerce and Industry provides for solving problems in many areas: for example, ensuring the manufacturability of the product design; design of technological processes and development of technological documentation; design and manufacture of technological equipment; organization and management of the process of technological preparation of production [8]. As a rule, production automation and manufacturing processes come down to the typification of design elements and technological processes [9], although in conditions of single and small-scale production this approach may not be effective due to the high costs of preparatory work [10].

This work is aimed at building a simulation model in order to reduce the duration and labor intensity of technological preparation of single and small-scale production, and increase the efficiency of production processes.

To build a new simulation model, it is necessary to use an analysis of various technological processing routes and the technological equipment used. One of the most effective methods for assessing many options for technological processes and selecting the most suitable one is simulation modeling of production processes and multi-criteria analysis based on a selected set of criteria [11,12]. When speaking about technological preparation of production, the authors will further refer to its model.

One of the factors for increasing the efficiency of an enterprise and its competitiveness is the automation of production processes [13]. Production processes also include technological preparation of production, the automation of which through digitalization ensures not only a reduction in production preparation time, but also optimizes the overall costs of manufacturing products. In addition, such automation ensures and allows you to adapt the technological process to changes in external conditions and quickly recalculate the technological process [14].

The main approaches of modern TPP models include: the theory of computational complexity, analysis of design and technological elements, analysis of the similarity of design solutions, and a scheduling system.

Complexity theory, as the basis of TPP, allows one to calculate the complexity of a system based on the complexity of the elements included in the system [15–17]. The complexity of the system ( $S$ ) can be represented as the sum of the products of the complexity of an element of a certain type ( $S_i$ ) and the number of such typical elements ( $k_i$ ):

$$S = \sum_{i=1}^n S_i \cdot k_i \quad (1)$$

Along with the complexity of individual elements of the system, an assessment is made of the complexity of the relationships between them and the load on the system with connections.

This theory was used as the basis for a number of techniques aimed at increasing the efficiency of the TPP. These methods allow, based on the analysis of time indicators: the duration of the production cycle and the amount of interoperational breaks, to design many technological processing routes for a batch of products, but do not allow estimating the production costs for producing a batch [18–20].

The theory, based on the analysis of design and technological elements (hereinafter referred to as DTE), makes it possible to increase the efficiency of TPP through various strategies and selection of equipment [21–23]. If we imagine the final product as a set of DTE, i.e. elementary surface or a set of elementary surfaces that have a common design purpose and are characterized by a common manufacturing route, then the DTE can be described by characteristic parameters. These include: the diameter of the DTE, the ratio of the length of the DTE to the total axial length of the part, the location of the material for cylindrical surfaces (inside/outside), the shape of the generatrix for surfaces obtained by rotating the generatrix around the axis of rotation of the part or other features of the shape of the DTE, the location of the DTE in detail. Assessing the degree of compliance of a cutting tool with a number of criteria allows one to set an algorithm for selecting the optimal set of tools [24].

Different strategies for using a selected set of tools allow you to construct a set of possible outcomes, that is, the order in which these tools are used. Strategies take into account machine processing time and tool change time, its cost and other costs (for example, the cost of processing an elementary surface).

Using mathematical apparatus, a multicriteria optimization problem was formulated, setting the significance of the criteria described above by weighting coefficients ( $a_i$ ) [25]:

$$J(x) = \sum_{i=1}^m a_i \cdot f_i(x); a > 0, \sum_{i=1}^m a_i = 1, \quad (2)$$

where  $f_i(x)$ ; – one of the criteria for the processing strategies under consideration.

This technique makes it possible to construct instrumental strategies for processing DTEs and determine the parameters of the tools used in them. However, this technique does not take into account an important parameter - the accuracy of DTE processing.

The methodology for analyzing the similarity of design solutions during technological preparation of production is based on the formalization and comparison of design and technological solutions [26–28]. The basic concept of this technique includes a technological complex (hereinafter referred to as the T-complex), which is a set of various standard surfaces for which there is a trajectory in which these surfaces can be processed together. Such complexes correspond to certain technological methods, used separately or in combination, depending on the expected production conditions and workmanship. T-complexes are characterized by: types of incoming surfaces; indicators of production and operational quality; external attributes of the connection of this complex with the others. These connections can be represented in the form of a model - a graph, the nodes of which are the identifiers of the selected T-complexes, and the edges are the corresponding connections between them. The connection graph makes it possible to estimate constructive similarity in two ways: by the composition of T-complex models and by the structure of connections of T-complexes [29,30]:

$$S = \frac{2m}{b+c} \quad (3)$$

where  $S$  - the value of the selected assessment of the design similarity of the part models.

Depending on the selected method, different values are associated with the parameters.

The disadvantages of this approach include incomplete consideration of the design of the part and its technical parameters and the inability to evaluate many options for technological processing routes. As a result, the duration of the production cycle and the amount of production costs are not determined accurately.

The TPP scheduling system is based on the calculation of time intervals between already planned operations for a given set of parts planned for production in the time period under consideration [31–33]. In the process of scheduling, the complexity of performing each operation on specific equipment is assessed; processing time for individual technological operations, as well as the total processing time for a given technological route; equipment downtime during processing of technological routes. Thus, based on the results of successfully implemented technological routes, it is possible to determine the most suitable equipment that has the best performance for still unprocessed routes. The criterion of minimizing service time is a solution to the problem of optimizing the production process [34]:

$$k_{1(i)} = \min (\sum_{I \in I_S} W_{ij}) \quad (4)$$

where  $W_{ij}$  – time interval between the end of the  $(j-1)$ -th and the beginning of the  $j$ -th operation of the  $i$ -th part;

$I_s$  – many order details S.

Planning is carried out taking into account the loading of technological equipment for processing the  $i$ th part.

Minimization of the time required to complete all work on a given set of parts is carried out using the following formula:

$$k_3 = \min (\sum_{I \in I_S} R_{ik} - \sum_{I \in I_S} F_i), \quad (5)$$

where  $R_{ik}$  - the amount of work that needs to be performed on the  $i$ -th order detail S.

With this theory, planning of technological processes is carried out on the basis of available data on successful implementations of similar or identical technological processes. Single and small-scale production involves the production of complex products in a small series or single copy, which makes it impossible to use this model. The use of equipment with the highest productivity for all identical technological routes does not allow optimizing the overall duration of the production cycle, as well as the loading of all available equipment. In addition, this model does not take into account production costs.

Thus, methods based on complexity theory make it possible to design many technological processing routes, but do not allow estimating production costs for the manufacture of a given batch

of products. The methodology for analyzing design and technological elements makes it possible to determine strategies for processing DTE and the necessary parameters and tools used in them. Unfortunately, the parameters used do not take into account the accuracy of DTE processing. Methods based on the method of similarity of design solutions do not allow taking into account the design features and technical parameters of the product. In addition, the methodology does not allow us to evaluate many options for technological processing routes, as well as determine the duration of the production cycle with a high degree of accuracy. The scheduling method does not allow for correction of the start time of already existing technological routes. Such a limitation leads to a significant limitation in the total number of final production scenarios and does not allow choosing the most optimal variant of the production process.

Therefore, the scientific novelty of this work is the construction of a simulation model that describes the method for selecting the best option for the production process of technological preparation of single and small-scale production based on multi-criteria analysis. The purpose of the article is to increase the efficiency of technological preparation of single and small-scale production based on simulation modeling of technological processes. The objectives of the study are to identify the main criteria for choosing a rational variant of the technological process, implement a simulation program for single and small-scale production with the possibility of multi-criteria analysis based on selected criteria, and test the implemented program for simulating the manufacture of the "Pusher" part.

## 2. Materials and Methods

The main task of creating a model is to select the optimal scenario for the operation of a production site based on the given data.

It must be taken into account that, depending on the equipment used and processing methods, the same product may have many solutions [35,36].

As part of the work, a generator of implementations of technological processes for the production of a given range of products on a given equipment (hereinafter referred to as ITTP) was built. The main task of the ITTP is to generate the largest possible number of possible implementation options at both the structural and parametric levels.

The generation of various implementations occurs by searching through all possible priorities of processing operations for given technological processes. Each technological process, as well as equipment, is given a priority in the form of positive integers. Moreover, as the number increases, the priority increases. The given priorities of the technological process play a role in the selection of the application, and the priorities of the equipment are responsible for the order of selection of equipment for the implementation of the technological route. If, in the process of servicing an application, a request with a higher priority arrives, servicing the current application is not interrupted, and the received application awaits its turn.

Similarly, priorities determine the sequence of selecting applications from sources, that is, parts corresponding to certain technological processes, as well as the sequence of their processing on a given technological equipment.

As a result of the completion of all these procedures, the output of the ITPP results in a fairly extensive set of implementations, among which it is necessary to select options that suit the relevant decision maker.

Thus, we have a multicriteria problem with  $m$  objective functions defined on some finite set  $D$  [37].

Problems of multicriteria optimization of technological processes arise at different stages of modeling. Within the framework of a given specific structural implementation of a technological process, "continuous" problems may arise related to the multi-criteria choice in the space of such continuous variables as the processing time of parts on various machines, processing costs, cost of machine downtime, etc. Similar problems can be solved for all possible (generated) structural implementations. At the next level of modeling, when all particular implementations have been optimized according to their controllable parameters, we have a finite set of implementations and

each element of this set has a vector estimate - the implementation time of the technological process, the cost of implementation, the downtime of machines, etc. The number of structural implementations generated can be quite significant.

Thus, the task arises of automating the decision-making process for choosing a rational option for implementing a technological process in accordance with the system of preferences of the decision maker. Such problems belong to "discrete" multicriteria selection problems.

When designing appropriate decision support systems, one can focus on existing methods of multi-criteria selection [37–40].

### 2.1 Structure of the simulation model and description of the simulation process

The research methodology and multicriteria solution are based on the application of Pareto principles and the associated concepts of effective (Pareto - optimal) and weakly effective solutions [41–43]. We consider a multi-criteria optimization problem of the form:

$$f_i(x) \rightarrow \max, \text{npu } x \in D \quad (6)$$

$$f_i: D \rightarrow R, i = 1, \dots, m; \quad (7)$$

$$D \subseteq R^m \quad (8)$$

Thus,  $m$  functions or functionals  $f_i$  are given, mapping the set of  $D_n$  - dimensional vectors  $x = (x_1, \dots, x_n)$  into the set of real numbers  $R$ . The choice of optimal values of the controlled parameters ( $x$ ) is not made in the entire  $n$ -dimensional space  $R_n$ , but only within its subset  $D$ .

Problem (8) can be represented as a problem of optimal selection of parameters  $(x_1, \dots, x_n)$  of some system, which is assessed by quality indicators  $(f_1, \dots, f_m)$ . In this case, the limitation  $x \in D$  reflects our technological and other possibilities for realizing certain values of  $x_i$ . In particular, the processing times for parts on machines and other equipment are obviously non-negative. Some restrictions can be formed on the basis of available information, which makes it possible to exclude obviously unsuccessful options  $x$  from consideration.

To solve the posed multicriteria problem in the study, we will use the linear convolution method.

This method of "scalarization" (convolution) of problem (8) allows us to replace the vector optimality criterion  $f = (f_1, \dots, f_m)$  with a scalar one  $J: D \rightarrow R$ . It is based on the linear combination of all partial objective functionals  $f_1, \dots, f_m$  into one:

$$J(x) = \sum_{i=1}^m \alpha_i f_i(x) \rightarrow \max; \text{ at } x \in D; \alpha_i > 0, \sum_{i=1}^m \alpha_i \quad (9)$$

In this case, the weighting coefficients  $\alpha_i$  can be considered as indicators of the relative importance of individual criterion functionals  $f_i$ . The more importance we give to the criterion  $f_j$ , the greater the contribution it should make to the sum and, therefore, the greater the value of  $\alpha_j$  should be chosen. In the presence of significantly different private criteria, it is usually quite difficult to indicate the final set of coefficients  $\alpha_i$ , based on informal considerations associated, as a rule, with the results of expert analysis.

The above-described method for solving the posed multicriteria problem does not allow identifying a single optimal solution. Solutions corresponding to different sets of weighting coefficients are equal elements of sets of effective and weakly effective solutions, which, according to the general formulation of the choice problem, implement the kernels of the corresponding binary relations (Pareto relations and Slater relations), i.e. and are the required solutions. However, from a practical point of view, for example, in problems of choosing options for the rational organization of technological processes, additional information about the preferences of the decision maker should be involved. The Pareto principle in this sense only allows us to narrow the class of possible candidates for a solution and exclude obviously uncompetitive options from consideration.

Methods for selecting a single solution to a multicriteria problem exist and are associated with the use of models and procedures designed to structure and quantitatively describe the subjective opinion of the decision maker (technologist). These methods are not discussed in this paper.

### 3. Result

#### 3.1. Structure of the Simulation Model and Description of the Simulation Process

The main task is to analyze the maximum possible number of options for processing technological routes for given products, in order to select the optimal work scenario according to two criteria: time and cost of processing.

A simulation model of technological preparation of production can be presented as a three-level model with network-centric control [44–46], where:

Level 1: Management of technological macro-operations (hereinafter referred to as MO - these are sequences of messages exchanged between the built-in controllers of first-level objects and second-level computers that control the implementation of the technology) of machine tools and robots. Each element of the production system is monitored, i.e. the following is carried out: analysis of the current state of each element of the production system; checking the correct execution of current actions of each of the elements of the production system; transmission of data indicating the beginning or completion of any actions of elements of the production system, as well as errors in their operation. At the first level, control of each element of the production system is carried out.

Level 2: Management and control of technological processes, described in the form of sequences of macro-operations: the interaction of elements of the production system is monitored, as well as the transmission of data on the state of network objects and their environment to the third level. At the second level, the interaction of elements of the production system is monitored, as well as the transmission of data on the state of network objects and their environment to the third level.

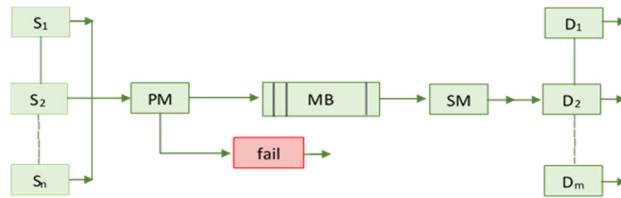

Level 3: Multi-criteria hierarchical optimization and planning of production processes. At the third level, the “data lake” is analyzed, on the basis of which dynamic planning of the workshop is carried out. When planning, the execution of MO by production network objects is optimized, which takes into account the possibilities of parallel execution of MO, their synchronization, areas of acceptable values of state parameters, conditions for reliable execution of the plan, etc. Since specific success criteria are defined for each operating mode of each network object, the third level must solve the problems of multi-criteria planning, as well as deriving new or changing existing control rules or assessing the state parameters of network objects.

Within the framework of this study, the third level of the model is considered, at which the modeling and analysis of various options for technological processing routes and the technological equipment used for each batch of parts is carried out. The model under consideration will be implemented as a queuing system (hereinafter referred to as QS) [47].

QS are models of systems into which applications (requirements) are received at random times from outside or inside. Each application received into the system must be serviced by the system. The service system is a set of maintenance equipment and personnel with the appropriate organization of the maintenance process. The basic concepts of QS include [48]:

1. A source that generates applications, and a set of sources creates the input flow of applications into the system. As a rule, sources can be of two types - finite and infinite, which differ in the methods of generating requests.
2. Buffer memory (storage location of the request queue). As a rule, it is divided into two types: general and zone. The shared memory stores requests from various sources, and the order in which they are recorded is determined only by the buffering discipline. Zone memory is a buffer divided into zones, each of which records requests only from a specific source. Thus, the number of zones corresponds to the number of sources.
3. Devices that service requests and create an output stream of requests after servicing.
4. Arrangement manager: sends a request for service or to buffer memory if there are no free devices; organizes the refusal or knocking out of an application from the buffer memory if there are no free places left in the buffer.
5. Selection manager: selects the device on which applications will be processed; selects a request from the memory buffer, if it exists there

Figure 1 shows the standard structure of the QS:

**Figure 1.** An example of the structure of a queuing system, where  $Si$  ( $i = 1 \dots n$ ) – sources, PM – production manager, MB – memory buffer, SM – selection manager,  $\Pi i$  ( $i = 1 \dots m$ ) – device.

Unlike the standard structure, the following changes were made to the implemented model:

1. The sources in the model are technological processes (hereinafter referred to as TP). TP represents a strict sequence of operations: from the delivery of blanks and tools from the warehouse to the machines, to the receipt of finished products of a given nomenclature at the warehouse. At the same time, the execution times of all operations are clearly specified.
2. No buffer memory.
3. The system cannot skip individual stages of the process, therefore it works flawlessly
4. The number of devices in the system depends on the specified technological equipment necessary for the implementation of the specified technological processes.
5. During the modeling process, applications are generated - a separate stage of the technological process. At the same time, the system processes one instance of each technological process. Thus, the number of applications in the system does not exceed the total number of technological processes.

### 3.2. Algorithmization of simulation modeling

To analyze the maximum possible number of options for technological processing routes for given products, in order to select the optimal work scenario according to the criteria of processing time and cost, the simulation algorithm can be divided into four main stages: processing user input, preparatory stage, the process of generating implementation options and choosing the optimal operating scenario (Figures 2 and 3).

User task: set the following input data for the correct operation of the simulation model:

1. A set of TPs and the number of implementations of each of them, that is, a list consisting of the type of operation, time and cost of implementation.
2. A set of technological equipment - one unit of a given equipment corresponds to one or more types of operations performed.

The preparatory stage consists of creating processors and sources of requests, taking into account the information received from the user.

The main stage is the operation of the ITTP. The process of generating implementation options allows you to generate the largest number of possible implementation scenarios by enumerating the priorities of operations for processing given data. Priorities allow you to set the sequence of selecting applications from sources, that is, parts corresponding to certain technological processes, as well as the sequence of their processing on specified equipment (machines) [49].

The selection of the optimal operating scenario is made using the linear convolution method [50,51].

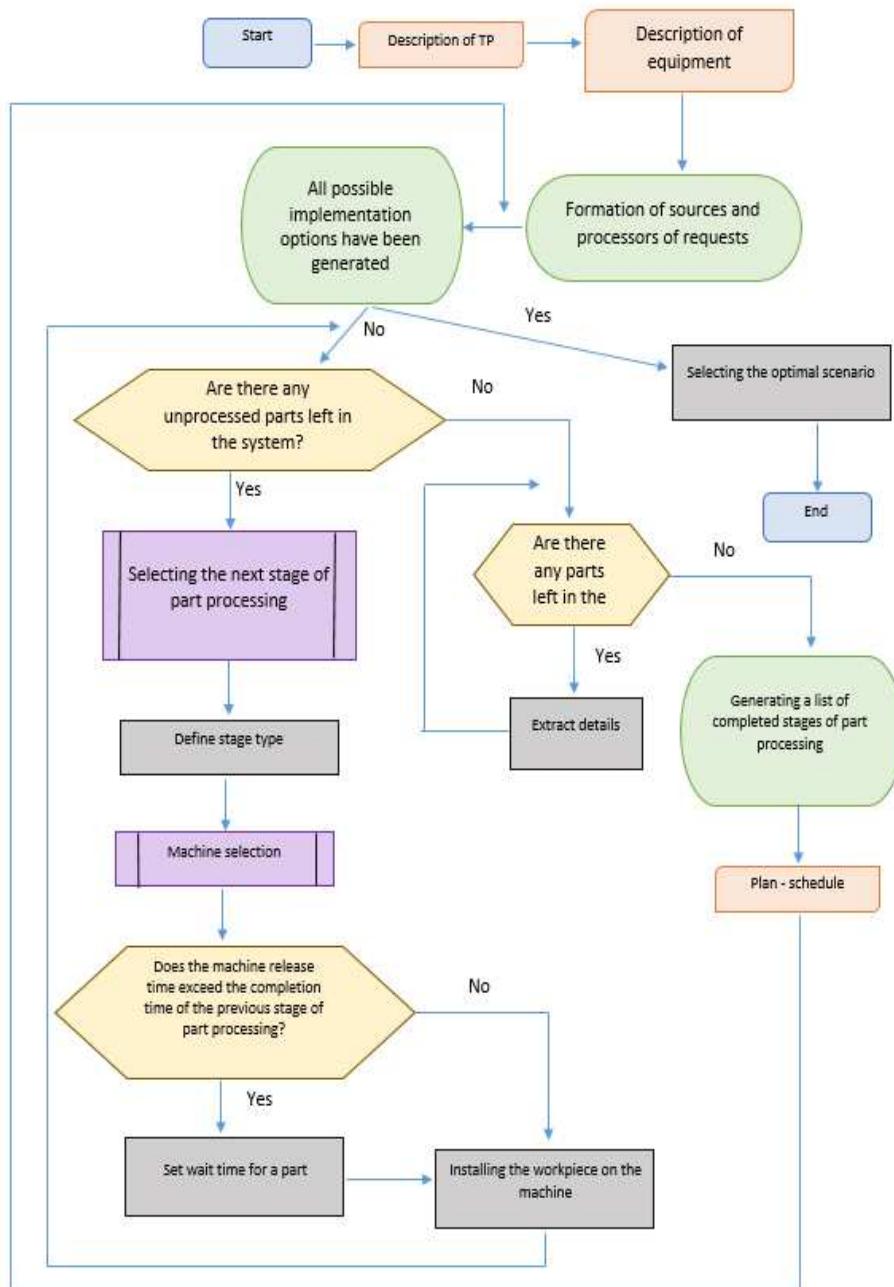

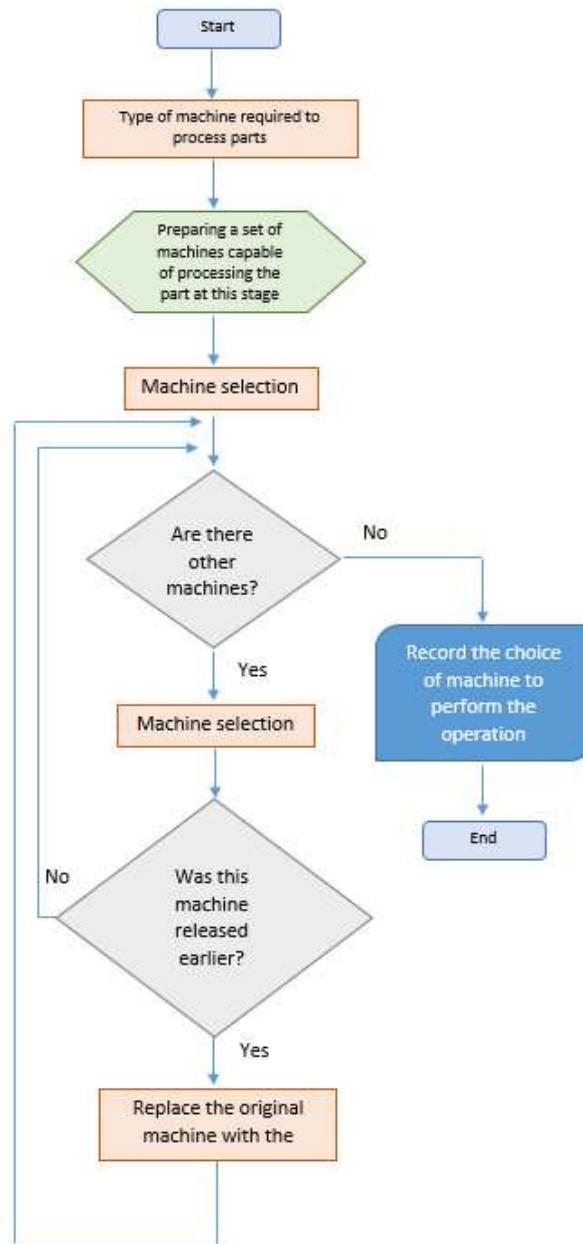

Figure 2. Simulation model algorithm diagram.

**Figure 3.** Scheme of the technology process description algorithm (TP).

A simulation model consists of a set of simple elements, designed as basic abstractions. Based on these concepts, it is possible to formulate a basic algorithm for the implemented component of the simulation model.

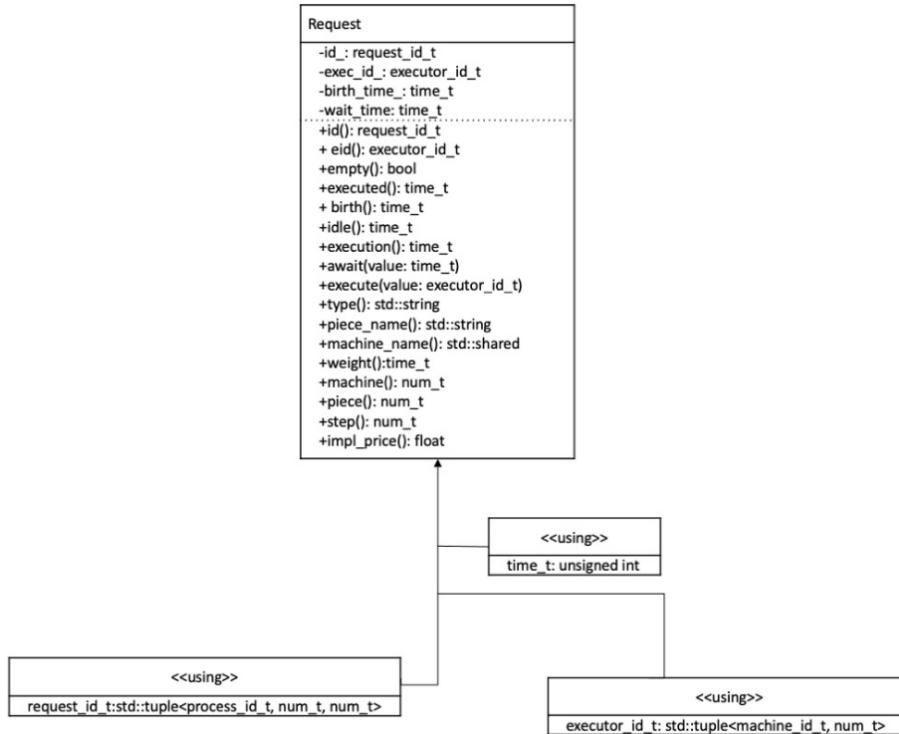

To implement the TP, it is necessary to consistently perform all its stages. Each such stage can be represented in the form of a simulation model application. The application must contain the following information:

1. Number of the TP implemented in the system (represented by the `id_` field);
2. Operation number in this TP (`id_`);
3. TP implementation number (`id_`);
4. Time of appearance of the application in the system (`birth_time_`).

New requests in the system await the release of technological equipment capable of performing the corresponding technological operation. When submitting a service request, the waiting time

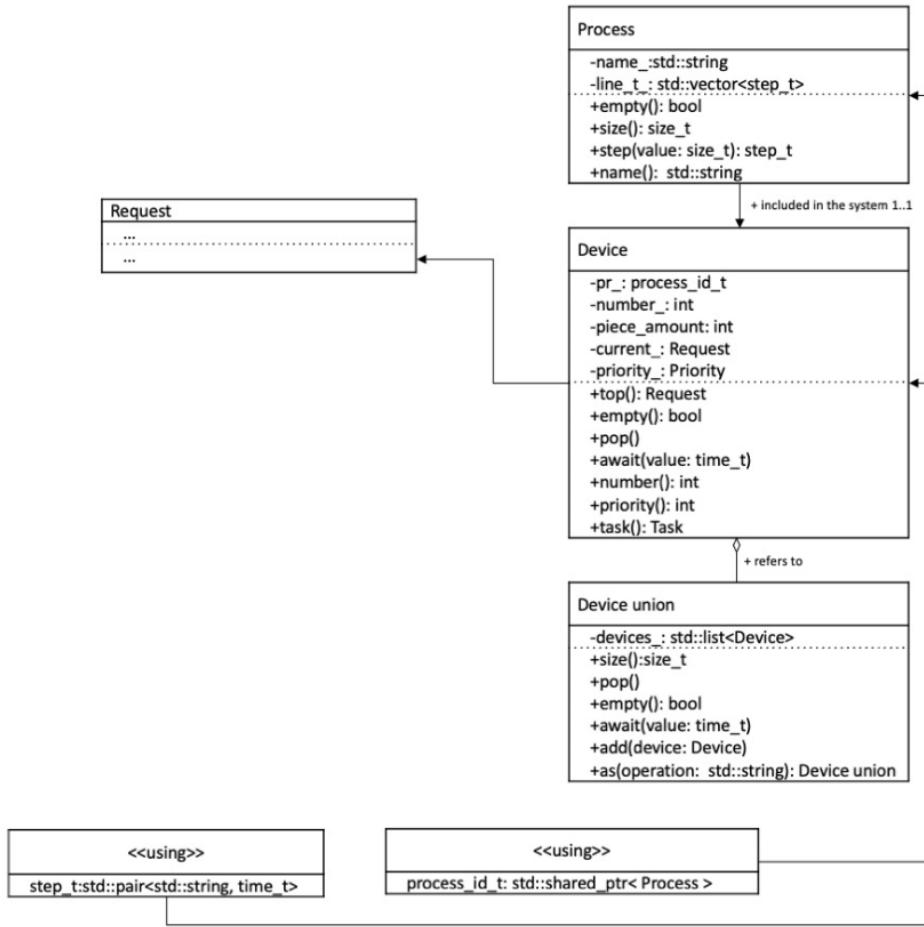

(`wait_time_`) and the contractor's identifier (`exec_id_`) are recorded. Thus, for each implementation of a technological process, it is possible to calculate the delay time for performing technological operations. A detailed diagram of the Request class is presented in Figure 4.

TPs are presented in the system in the form of application sources, which records the number of implementations of one of the TPs and generates a unique application identifier. The execution of the TP process is repeated until the specified number of implementations has been completed. Since the TP stages are performed sequentially, each source provides only one application at a time. Thus, the number of requests in the system corresponds to the number of parallel processing processes. This pool of orders can be managed: for example, you can select orders of a certain type of operation.

**Figure 4.** UML diagram of the Request class.

The pool of applications is managed by the `Device_union` class. Order sources are represented by the `Device` class, and TPs are represented by the `Process` class. Figure 5 shows a detailed UML diagram of the listed classes and their relationship with the Request class.

**Figure 5.** UML diagram of technological processes and sources of requests.

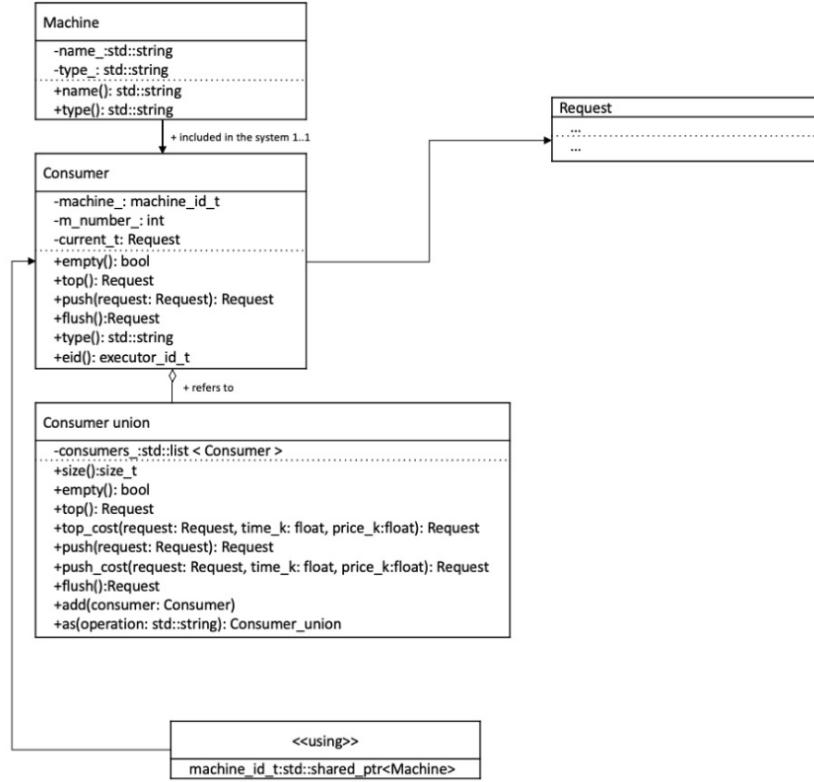

Technological equipment is represented by the **Machine** class, containing the following information:

1. Name of the process equipment (represented by the **name\_** field)
2. Types of operations performed (**line\_**)

The resources of a specific piece of technological equipment are managed by the **Consumer** class, which stores information about the last completed request. The information contained in the application is sufficient to determine the readiness of a certain piece of technological equipment to process the next application.

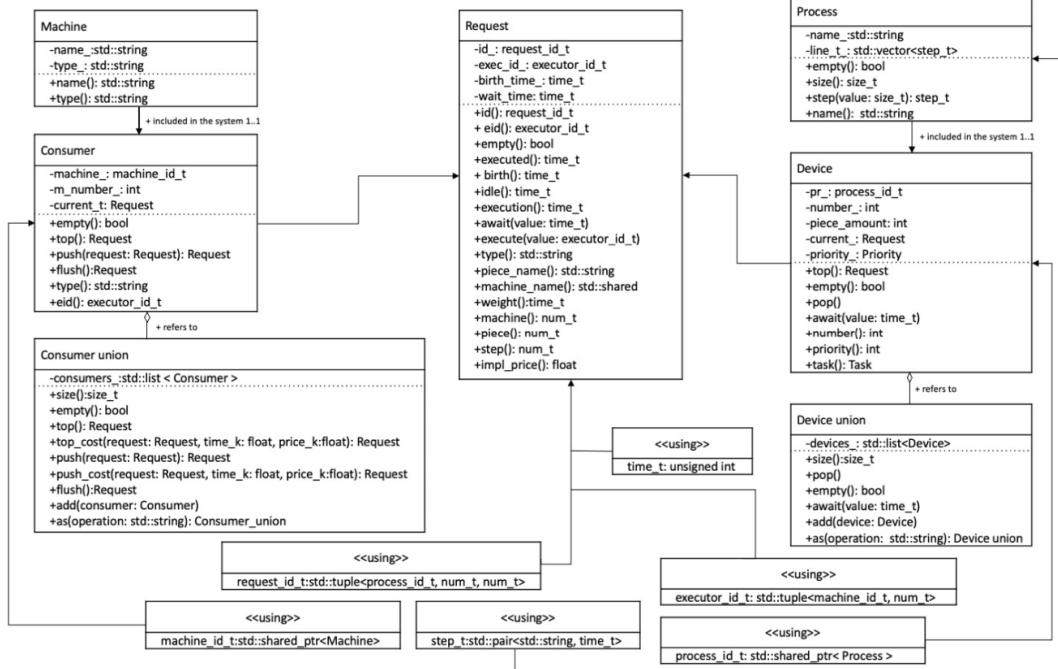

During the modeling process, the **Consumer\_union** class provides the required unit of technological equipment depending on the selected request, taking into account the priorities and readiness of the units of technological equipment.

Below is a detailed UML diagram of technological equipment and application processors (Figure 6).

**Figure 6.** UML diagram of technological equipment and application processors.

The complete class diagram is shown in Figure 7.

**Figure 7.** UML diagram of the complete simulation model.

## 4. Result and Discussion

In existing models based on queuing systems, the production manager sends requests either directly for service or to buffer memory. If there are no free devices, the dispatcher organizes a refusal

or knocking out the request from the buffer memory, if there are no free places left in the buffer, then the selection manager selects the device on which the requests will be processed, selects the request from the memory buffer, if it is there. This whole process, in turn, makes it difficult to parameterize the state of the network according to specific success criteria for each operating mode of a certain model object. In the proposed model, the number of devices in the system depends on the specified technological equipment necessary to implement the specified technological processes. Thus, in the proposed model there is no buffer memory, so the system cannot skip individual stages of the technological process, and therefore works flawlessly. During the modeling process, applications are generated as a separate stage of the technological process. At the same time, the system processes one instance of each technological process. Thus, the number of applications in the system is generated in such a way as not to exceed the total number of technological processes.

The developed simulation model was used in the process of modeling the technological preparation of production to simulate the manufacture of the "Pusher" part.

The manufactured part "Pusher" (Figure 8) has the following technical parameters:

1. Dimensions: maximum diameter 24mm, length 26mm;
2. Exact dimensions:  
outer diameter  $\phi 24h6$  with roughness Ra 0.8;  
internal diameter  $\phi 11H8$  with roughness Ra 1.6;  
internal threaded surface M8-7H, roughness Ra 3.2.
3. General tolerances for other dimensions: H14, h14,  $\pm IT14/2$ .

**Figure 8.** Solid model of the "Pusher" part.

Four types of machines are involved in the processing route:

- Thun – universal lathes
- Tchpu – lathes with numerical control
- TFNC – turning and milling machines with numerical control
- KSh – cylindrical grinding machines

Table 1 describes the types of machines and their methods for processing technological elements.

**Table 1.** Types of machine tools involved and their processing methods.

№	Machine type	Machine type designation	Processing method	Designation of
				processing method
1	Tun	mach1	tapping threads	op1
			drilling	op2
			semi-finish turning	op3
			rough turning	op4
			finishing turning	op5
2	Tcnc	mach2	tapping threads	op1

			drilling	op2
			semi-finish turning	op3
			rough turning	op4
			finishing turning	op5
			tapping threads	op1
			drilling	op2
			semi-finish turning	op3
3	TF <sub>CNC</sub>	mach3	rough turning	op4
			finishing turning	op5
			Pre-	
			grinding	op6
4	KS	mach4	Tapping threads	op1

In accordance with Table 1, the input data for the simulation model for the given equipment was formulated:

#### *Equipment*

```
(:consumer 0:worker (:machine "mach1":line ( "op1" "op2" "op3" "op4" "op5" ):factor 1.0:);)
(:consumer 1:worker (:machine "mach2":line ( "op1" "op2" "op3" "op4" "op5" ):factor 1.2:);)
(:consumer 2:worker (:machine "mach3":line ( "op1" "op2" "op3" "op4" "op5" ):factor 1.3:);)
(:consumer 3:worker (:machine "mach4":line ( "op6" ):factor 1.0:);)
```

#### Explanation:

- consumer № – identification number of the specified equipment;
- worker – information about the specified equipment;
- machine – name of the specified equipment;
- line – list of types of operations that can be performed on this equipment;
- factor – cost multiplier (the higher the value, the higher the cost of processing parts on this equipment).

For each block of surfaces, the following sequence of processing of the design and technological elements included in their composition was determined:

- MB(1/1): DTE(1H-1)1 → DTE(2H/2-1)2 → DTE(2H/1-1)2 → DTE(2H/2-1)1
- MB(1/2): DTE(1H-1)2 → DTE(2H/1-4)1
- MB(2/1): DTE(2B/1-2)1 → DTE(2B/1-1)2 → DTE(2B/2-1)1 → DTE(1B-1)1
- MB(2/2): DTE(2B/1-2)3 → DTE(2B/1-3)4 → DTE(2B/2-2)2 → DTE(1B-1)2 → DTE(1B-2)3
- MB(4/1): DTE(4B/1-2)1

For the "Pusher" part, the following sequence of processing of surface blocks was defined:

MB(1/2) → MB(2/1) → MB(1/1) → MB(2/2) → MB(4/1)

Technological elements included in the design and technological elements are processed sequentially.

The given surface blocks were divided into final operations (Table 2):

**Table 2.** Analysis of surface blocks for final operations.

<b>Nº</b>	<b>Block of surfaces</b>	<b>DTE</b>	<b>Processing method</b>	<b>Designation of processing method</b>
1	MB(1/2)	1 DTE(1H-1)2	rough turning	op4
			re-grinding	op6
			rough turning	op4
	MB(2/1)	2 DTE(2H/1-4)1	semi-finish turning	op3
			finishing turning	op5
			drilling	op2
2	MB(1/1)	1 DTE(2B/1-2)1	semi-finish turning	op3
			drilling	op2
		2 DTE(2B/1-1)2	drilling	op2
		3 DTE(2B/2-1)1	drilling	op2
	MB(2/2)	4 DTE(1B-1)1	rough turning	op4
		1 DTE(1H-1)1	rough turning	op4
		2 DTE(2H/2-1)2	rough turning	op4
		3 DTE(2H/1-1)2	rough turning	op4
		4 DTE(2H/2-1)1	rough turning	op4
		1 DTE(2B/1-2)3	drilling	op2
3	MB(4/1)	2 DTE(2B/1-3)4	semi-finish turning	op3
			drilling	op2
			semi-finish turning	op3
		3 DTE(2B/2-2)2	rough turning	op5
		4 DTE(1B-1)2	drilling	op2
		5 DTE(1B-2)3	semi-finish turning	op3
	MB(4/1)	1 DTE(4B/1-2)1	rough turning	op4
			semi-finish turning	op4

5	op5	finishing turning	16	7400

6	op6	re-grinding	29	5800
---	-----	-------------	----	------

In accordance with relation (7) and Tables 2, 3, the TP input data for the simulation model were formulated, input data of the simulation model for a given technological process:

#### *Technological Process*

```
(:device 0:task ((:process "TP-T":line (( "op4" (:time 40:price 13600:) ) ( "op3" (:time 12:price 8200:) ) ( "op5" (:time 16:price 7400:) ) ( "op6" (:time 29:price 5800:) ) ( "op2" (:time 18:price 5600:) ) ( "op3" (:time 12:price 8200:) ) ( "op2" (:time 36:price 11200:) ) ( "op4" (:time 100:price 34000:) ) ( "op2" (:time 18:price 5600:) ) "op3" (:time 12:price 8200:) ) ( "op2" (:time 18:price 5600:) ) ( "op3" (:time 12:price 8200:) ) ( "op5" (:time 16:price 7400:) ) ( "op2" (:time 18:price 5600:) ) ( "op3" (:time 12:price 8200:) ) ( "op4" (:time 40:price 13600:) ) ( "op3" (:time 12:price 8200:) ) ( "op2" (:time 18:price 5600:) ) ( "op1" (:time 32:price 4800:) )) 1:):)
```

#### Explanation:

- device № – identification number of the specified TP;
- task – information about a given TP;
- process – name of the specified TP;
- line – list of operations that make up the given TP:
- 1) time – processing time of a given operation;
- 2) price – the cost of processing a given operation;
- No. – number of implementations of a given TP

Presents the result of the simulation model in MRD (Machine-Readable Data) format, where:

- id – information about the application being processed;
- name – name of the TP;
- num – part number of the current TP;
- step – number of the operation being performed;
- type – type of operation being performed;
- birth – time of appearance of the current request in the system;
- price – cost of performing the current operation;
- wait – start time of processing the current request;
- executor – information about the equipment on which the application is processed:
- 1. name – name of the equipment on which the current request is being processed;
- 2. num – number of the equipment on which the current request is being processed;
- 3. execution – end time of application processing;
- 4. impl\_price – cost after the application is processed

A listing of the final schedule of the simulation model with the main set of cutting tools:

*Res\_price:175000 Res\_time: 471*

As a result of simulating the production of the “Pusher” part, the optimal scenario for the operation of the production site was selected according to two criteria of time and cost. The final duration of the production cycle was 471 working hours, the final value of variable costs was 175,000 conventional units, which confirms that the created algorithm and simulation model are adequate under the conditions of a single production. In the future, it is planned to develop a simulation model with an alternative set of cutting tools. Typically, the choice of cutting tool affects the processing time of the part and its cost.

## 5. Conclusions

In the article, the authors solved the problem of automating the decision-making process of choosing a rational option for implementing a technological process in accordance with the system of preferences of the decision maker. Such problems belong to “discrete” multicriteria selection problems.

The manuscript analyzed the models of technological preparation of production described in Russian and foreign sources. When analyzing scientific literature, models of technological preparation of production were considered, based on complexity theory, analysis of individual design and technological elements, analysis of the similarity of design solutions and scheduling.

As a result of the analysis of various methods and models aimed at increasing the efficiency of technological preparation of production, the following conclusions were made:

1. In most models of technological preparation of production, multi-criteria analysis is not used; the choice of the best options for technological processing routes and processing strategies for individual elements of a part is not described; it is made only on the basis of an analysis of the duration of the production cycle or the amount of production costs.
2. Methods for estimating the value of interoperational breaks, based on the method of mathematical statistics, do not allow an accurate assessment of the duration of the production cycle and highly accurate prediction of the production time of the product.
3. Methods based on the method of similarity of design solutions when designing a technological process do not allow taking into account all the design features of the part and its technical parameters, as well as assessing many options for technological processing routes and determining the duration of the production cycle with a high degree of accuracy.
4. A number of the described methods use a production process planning method based on the analysis of identical operations that have already been implemented in the conditions of a particular enterprise. This method does not provide high accuracy in single and small-scale production types due to the wide variety of design and technological solutions.
5. In the model of technological production preparation, based on the scheduling method, when forming a production schedule, adjustments to the start time of already existing technological operations are not allowed, which significantly limits the number of simulated production scenarios. Consequently, this does not allow choosing the most rational option for the production process.

To build a new simulation model, the authors used an analysis of various technological processing routes and the technological equipment used. One of the most effective methods for assessing multiple options for technological processes and selecting the most suitable one is simulation modeling of production processes and multi-criteria analysis based on a selected set of criteria.

Unlike the standard structure, the following changes were made to the implemented model:

1. The sources in the model are technological processes (hereinafter referred to as TP). TP represents a strict sequence of operations: from the delivery of blanks and tools from the warehouse to the machines, to the receipt of finished products of a given nomenclature at the warehouse. At the same time, the execution times of all operations are clearly specified.
2. There is no buffer memory.
3. The system cannot skip individual stages of the process, therefore it works flawlessly.
4. The number of devices in the system depends on the specified technological equipment necessary for the implementation of the specified technological processes.
5. During the modeling process, applications are generated - a separate stage of the technological process. At the same time, the system processes one instance of each technological process. Thus, the number of applications in the system does not exceed the total number of technological processes. As a result of the analysis, a simulation model algorithm was developed, UML diagrams were designed describing the structure of the system, classes, their attributes, methods and relationships between objects.

A simulation program has been developed in C++ for single and small-scale production, with the aim of automating the process of technological processing by automatically generating the largest number of work scenarios and further selecting the optimal scenario for the production site according to two criteria of time and cost.

As a result of simulating the production of the "Pusher" part, the final duration of the production cycle was 471 working hours, the final value of variable costs was 175,000 conventional units.
