Abstract: Receptor-interacting protein kinase 1 (RIPK1) plays a crucial role in controlling inflammation and cell death. Its function is tightly controlled through post-translational modifications, enabling its dynamic switch between promoting cell survival and triggering cell death. Phosphorylation of RIPK1 at various sites serves as a critical mechanism for regulating its activity, exerting either activating or inhibitory effects. Perturbations in RIPK1 phosphorylation status have profound implications for the development of severe inflammatory diseases in humans. This review explores the intricate regulation of RIPK1 phosphorylation and dephosphorylation and highlights the potential of targeting RIPK1 phosphorylation as a promising therapeutic strategy for mitigating human diseases.

Introduction

Receptor-interacting protein kinase 1 (RIPK1) plays a crucial role in regulating inflammation and cell death. Recent findings indicate that both genetic mutations and non-genetic factors influencing RIPK1 activity can lead to a range of inflammatory and degenerative diseases, highlighting the necessity for precise regulation of RIPK1 function in maintaining human health^{1,2}.

The full-length human RIPK1 protein consists of 671 amino acids, with a molecular mass of approximately 76 kDa, sharing 68% identity with its mouse counterpart (Figure 1). Belonging to the RIP kinase family, RIPK1 is one of seven members, each featuring a homologous kinase domain (KD). Besides the common N-terminal kinase domain, RIPK1 possesses a C-terminal death domain (DD), facilitating its own dimerization or interaction with other death domain-containing proteins like TNFR1 (tumor necrosis factor receptor 1), TRADD (TNFR1-associated death domain protein) and FADD (Fas-associated death domain)³. Additionally, RIPK1 contains a bridging intermediate domain (ID) housing a RIP homotypic interaction motif (RHIM)⁴. The RHIM domain of RIPK1 facilitates its self-polymerization to form amyloid fibers⁵. It also allows interaction with other RHIM-containing proteins such as RIPK3, ZBP1 (Z-DNA binding protein 1, also known as DAI and DLM-1), and TRIF (TIR-domain-containing adapter-inducing interferon β)^{1,2}.

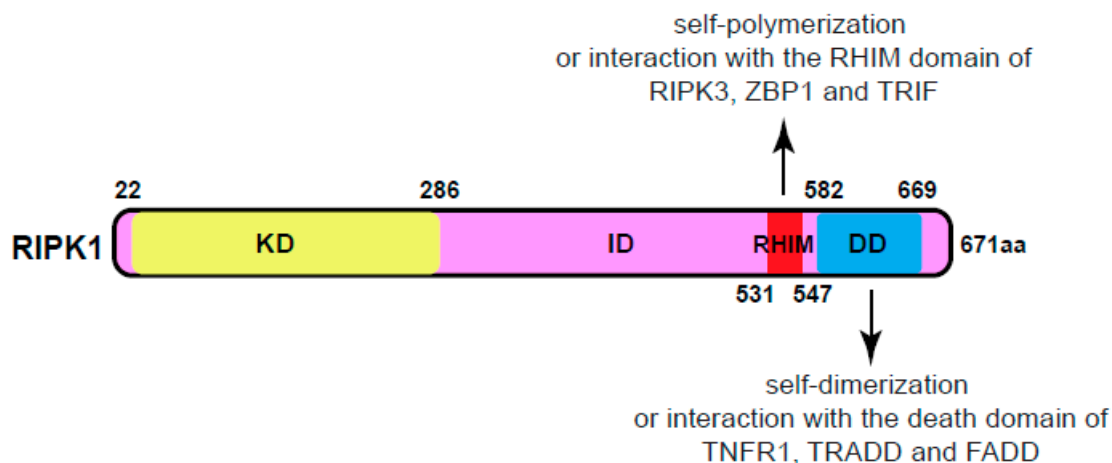

Figure 1. Domain structure of RIPK1. KD, kinase domain. ID, intermediate domain. RHIM, RIP homotypic interaction motif. DD, death domain. RIPK1, receptor-interacting protein kinase 1. TRIF, TIR-domain-containing adapter-inducing interferon β .

RIPK1 primarily regulates inflammation through its scaffold function, while its involvement in cell death requires its kinase activity. The regulation of RIPK1 function involves various post-translational modifications, including ubiquitination, phosphorylation, and glycosylation. This review aims to summarize RIPK1's impact on inflammation, cell survival, cell death, development and disease pathogenesis, with a focus on the role of phosphorylation and dephosphorylation.

RIPK1-Mediated Prosurvival and Inflammatory Signaling

RIPK1 was initially reported to strongly interact with the cell surface receptor Fas/APO-1 (CD95) and weakly with TNFR1⁶. Subsequently, various members of the TNF superfamily, including TNF α , FasL, and TRAIL (TNF-related apoptosis-inducing ligand), were found to induce RIPK1-mediated NF κ B activation³. Among these, the TNF α cascade has been extensively studied (Figure 2)⁷. Upon TNF α binding, RIPK1 and TRADD are rapidly recruited to TNFR1, initiating the assembly of complex I through mutual interactions between their death domains⁸⁻¹⁰. TRADD then recruits adaptor proteins TRAF2 and 5 (TNF receptor-associated factor protein 2/5), which in turn engage the E3 ubiquitin ligases cIAP1/2 (cellular inhibitor of apoptosis 1 and 2)^{11,12}. cIAP1/2 catalyzes K63 ubiquitination of RIPK1, serving as a scaffold to recruit ubiquitin-binding proteins TAB2/3 (TAK1-binding protein 2/3) and TAK1 (transforming growth factor- β -activated kinase 1)^{13,14}. TAK1 then activates the MAPK (mitogen-activated protein kinase) pathway, including p38 and MK2 (MAPK-activated kinase 2)¹⁵. Additionally, the K63 ubiquitin chain recruits another E3 complex LUBAC (the linear ubiquitin chain assembly complex), which catalyzes the M1 linear ubiquitin chains on RIPK1 and TNFR1^{16,17}. These linear ubiquitin chains recruit adaptor protein NEMO (NF κ B essential modulator), which further engages IKK α/β (I κ B kinase α/β) and TBK1/IKK ϵ ¹⁸⁻²⁰. IKK α/β subsequently activates NF κ B pathway^{21,22}. Both the MAPK pathway and the NF κ B pathway activate gene expression that promotes cell survival and inflammation to suppress cell death^{7,15}.

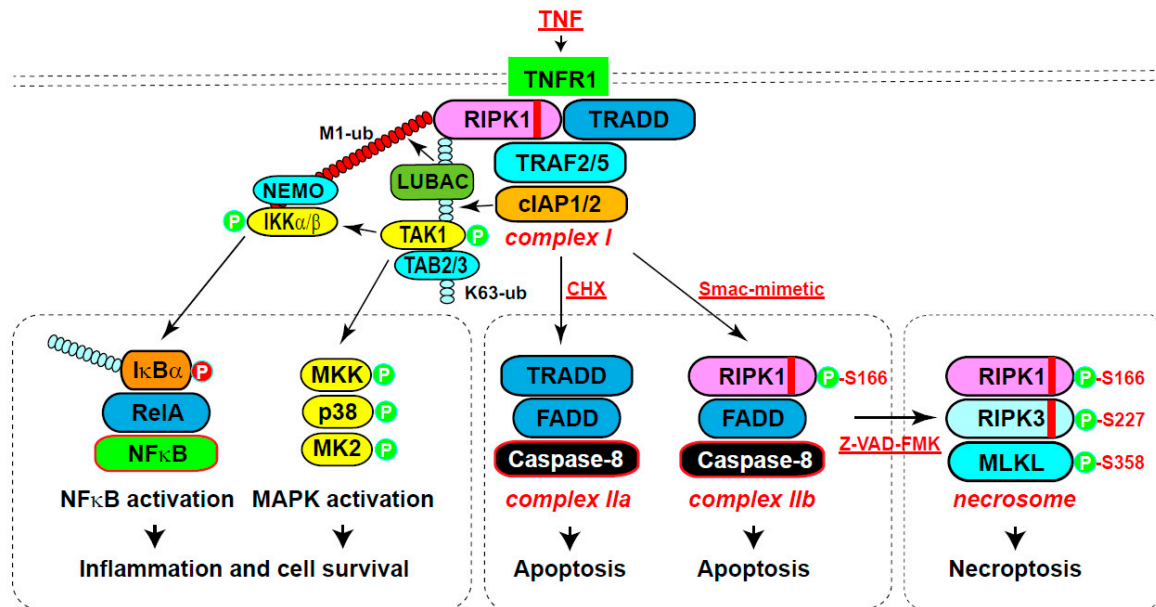

Figure 2. Pleiotropic TNF signaling pathways. (1) Inflammation and cell survival. Engaging of TNF with its receptor TNFR1 leads to the recruitment of RIPK1 and TRADD through death domain interactions to initiate complex I formation. TRADD then recruits adaptor protein TRAF2/5, which binds E3 ligase cIAP1/2. cIAP1/2 catalyzes K63 ubiquitination of RIPK1, serving as a scaffold to recruit ubiquitin-binding proteins TAB2/3 and associated TAK1, activating downstream MAPK pathway. Additionally, the K63 ubiquitin chain recruits another E3 complex LUBAC, which catalyzes the M1 linear ubiquitin chains on RIPK1 and TNFR1. These linear ubiquitin chains recruit adaptor protein NEMO and associated IKK α /b, phosphorylating I κ B α to promote its degradation and subsequent NF κ B activation. Both the MAPK pathway and the NF κ B pathway activate gene expression that promotes cell survival and inflammation. (2) Apoptosis. Under TNF treatment with protein synthesis inhibition by cycloheximide (CHX), complex I is converted to complex IIa, containing TRADD, FADD and Caspase-8, leading to oligomerization and activation of Caspase-8 and subsequent apoptosis. Alternatively, co-treatment of TNF with a cIAP1/2 inhibitor Smac-mimetic converts complex I to complex IIb, containing RIPK1, FADD and Caspase-8, which also activates Caspase-8 and apoptosis. (3) Necroptosis. Inhibition of apoptosis with Z-VAD-FMK, along with the presence of RIPK3, leads to the conversion of complex II into the necrosome. The core components of necrosome includes RIPK1, RIPK3 and MLKL, resulting in polymerization and membrane translocation of MLKL and subsequent cell death. In general, the scaffold function of RIPK1 is important for inflammation and cell survival, while the kinase activity is important for complex IIb-dependent apoptosis as well as necroptosis. TNF, tumor necrosis factor. TNFR1, tumor necrosis factor receptor 1. TRADD, TNFR1-associated death domain protein. TRAF2 and 5, TNF receptor-associated factor protein 2/5. cIAP1/2, cellular inhibitor of apoptosis 1 and 2. TAB2/3, TAK1-binding protein 2/3. TAK1, transforming growth factor- β -activated kinase 1. LUBAC, the linear ubiquitin chain assembly complex. NEMO, NF κ B essential modulator. IKK α /b, I κ B kinase a/b. I κ B α , inhibitor of κ B alpha. NF κ B, nuclear factor kappa-light-chain-enhancer of activated B cells. MAPK, mitogen-activated protein kinase. FADD, Fas-associated death domain. MLKL, mixed-lineage kinase like protein.

RIPK1-Mediated Apoptosis

Apoptosis is regarded as a non-inflammatory form of programmed cell death, during which the contents of the dying cells are contained within apoptotic bodies. Caspases, a subfamily of cysteine proteases are both the initiators and executioners of apoptosis, as revealed by genetic and biochemical studies. Physiological and pathogen-related stimuli can trigger apoptosis through either extrinsic or intrinsic pathway. This process is vital for maintaining normal development and tissue homeostasis^{23,24}.

RIPK1 primarily mediates extrinsic apoptosis induced by death receptor ligands, such as TNF α , FasL and TRAIL, dependent on cellular context¹. Combining TNF α with a protein synthesis inhibitor cycloheximide (CHX), or an IAP antagonist Smac-mimetic can switch TNF α -induced inflammatory response to apoptosis (Figure 2)²⁵. CHX promotes Caspase-8 activation by eliminating endogenous Caspase-8 inhibitor c-FLIP, leading to the formation of complex IIa including TRADD, FADD and Caspase-8²⁶. On the other hand, Smac-mimetic triggers cIAP1/2 autodegradation, releasing RIPK1 from the complex I to form complex IIb consisting of RIPK1, FADD, and Caspase-8^{25,27,28}. Activated Caspase-8 cleaves the preforms of caspases-3/7 to execute apoptotic death. Activation of TNFR1 under various deficient conditions (TAK1, NEMO, TBK1, IKK α/β , A20 and ABIN1) also triggers RIPK1 activation and complex IIb formation, leading to RIPK1-dependent apoptosis²⁹⁻³⁵. Importantly, RIPK1 kinase activity is essential for TNF and Smac-mimetic-stimulated, but not for TNF and CHX-induced apoptosis, as demonstrated by RIPK1 knockdown, RIPK1 kinase inhibitor necrostatin, or kinase-dead mutants (K45A or D138N)^{10,25,36-38}.

RIPK1-Mediated Necroptosis

Necroptosis, a proinflammatory form of programmed cell death, is characterized by cell membrane rupture and the release of damage-associated molecular patterns (DAMPs). While not essential for embryogenesis, necroptosis plays a vital role in immune defense against pathogens and is implicated in various human diseases, including inflammation, tissue damage and neurodegeneration³⁹.

Necroptosis is initially suppressed by apoptosis, primarily through the cleavage of RIPK1 by activated Caspase-8 in complex II, for example, when induced by TNF and Smac-mimetic or CHX^{40,41}. However, when Caspase-8 is inactivated by specific inhibitors (such as Z-VAD-FMK) or genetic elimination, activated RIPK1 in complex IIb recruits RIPK3 through their respective RHIM domains, initiating the formation of another protein complex called the necrosome (Figure 2)^{5,42-46}. Oligomerized RIPK3 then recruits the casein kinase 1 family proteins CK1 $\alpha/\delta/\epsilon$ which phosphorylate Ser227 of human RIPK3⁴⁷. Phosphorylated RIPK3 subsequently recruits MLKL and phosphorylates human MLKL at Thr357 and Ser358^{48,49}. Consequently, MLKL undergoes oligomerization into tetramers and amyloid-like polymers, which translocate to the plasma membrane, resulting in plasma membrane permeabilization⁵⁰⁻⁵⁶. In addition, activated MLKL translocates to the lysosomal membrane, where it forms amyloid-like polymers to facilitate lysosomal membrane permeabilization and the release of lysosomal proteases, thereby promoting cell death⁵⁷.

RIPK1-mediated necroptosis requires its kinase activity, similar to its involvement in RIPK1-dependent apoptosis. For example, the RIPK1 inhibitor Nec-1 effectively prevents necroptosis induced by TNF, TLR-ligands and interferons^{43,58,59}. Moreover, mice with kinase-dead RIPK1 knock-in mutations are resistant to TNF-induced necroptosis and systemic inflammatory response syndrome (SIRS), similar to RIPK3 knockout mice, and demonstrate superior resistance compared to MLKL knockout mice^{38,60,61}.

Multiple innate immune signaling molecules, including death receptors (such as TNFR1), pathogen recognition receptors (such as TLR3 and TLR4), and cytosolic RNA sensor ZBP1, can induce necroptosis. Activation of these pathways all lead to the interaction of RHIM-containing proteins, such as RIPK1, TRIF or ZBP1 with the RHIM domain of RIPK3, activating RIPK3 and MLKL to promote necroptosis^{58,62-64}.

The role of apoptosis in suppressing necroptosis is crucial for embryonic development. Deficiency in apoptosis components, such as the knockout of Caspase-8 or FADD, often results in late gestation embryonic lethality, primarily due to hyperactivation of necroptosis^{65,66}. Simultaneous deletion of RIPK3 or MLKL can rescue the embryonic lethality of these mice, albeit with immune deficiencies in adulthood^{67,68 69}.

Phosphorylation of RIPK1

(1) Auto-activating phosphorylation

The serine-threonine kinase activity of RIPK1 is crucial for both complex IIb-dependent apoptosis and necroptosis⁷⁰. Typically, kinases adopt a closed conformation and require phosphorylation in the activation loop, also known as the T-loop, to activate their kinase activity⁷¹. These activating phosphorylation events can be catalyzed by upstream kinases or achieved through autophosphorylation. Currently, autophosphorylation is the only known mechanism for activating RIPK1 (Figure 3). For instance, autophosphorylation of S161 stabilizes the open conformation of the T-loop and promotes human RIPK1 kinase activation to induce necroptosis⁴³. Furthermore, mitochondrial reactive oxygen species (ROS) modify three essential cysteine residues of RIPK1, leading to cysteine-mediated aggregation of RIPK1 and subsequent autophosphorylation on S161, which is critical for RIPK1 to effectively promote necrosome formation and cell death⁷². Moreover, S166 autophosphorylation of RIPK1 is indispensable for MLKL activation and necrosome formation. Mutation of S166 effectively prevents multiple RIPK1 kinase-dependent inflammatory lesions *in vivo*, such as intestinal colitis, hepatitis, liver tumorigenesis, skin inflammation, and TNF-induced SIRS. Interestingly, while autophosphorylation of Ser166 is essential, it alone is not adequate to initiate RIPK1-mediated cell death⁷³. Multiple autophosphorylation sites, including serine residues 14/15, 20, 161, and 166, cooperate to induce conformational changes in RIPK1^{43,74}. These changes facilitate its association with cell death effectors such as FADD and RIPK3, promoting the assembly of cell death-inducing signaling complexes, such as complex II and the necrosome. It is noteworthy that recombinant RHIM domain of RIPK1 exhibits a significantly higher affinity toward itself than the RHIM domain of RIPK3⁵. Autophosphorylation of RIPK1 is thought to change its conformation, favoring the interaction between the RIPK1 and RIPK3 RHIM domains over the interactions between RIPK1 RHIM domains, thereby promoting necrosome formation⁴⁷.

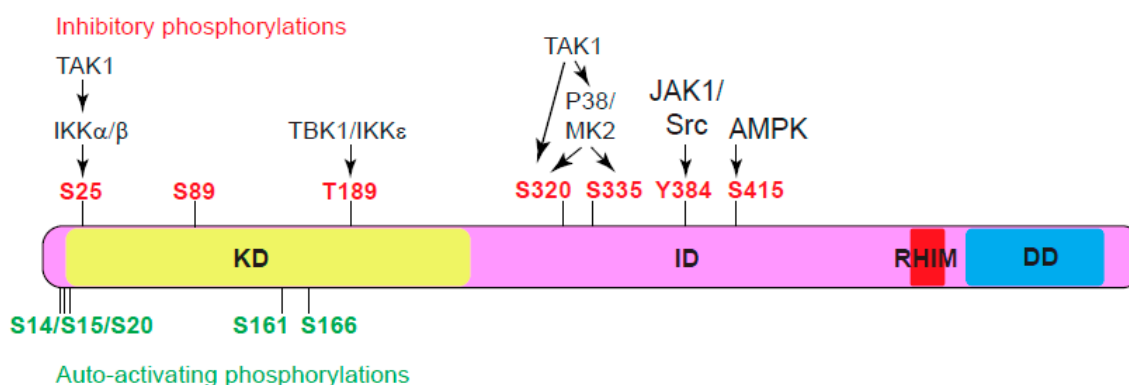

Figure 3. Phosphorylation events impacting RIPK1 kinase activity. In this context, green character denotes auto-activating phosphorylation, while red character denotes inhibitory phosphorylation. Notably, the kinase responsible for S89 phosphorylation has not yet been reported. TBK1, TANK-binding kinase 1. IKKe, IκB kinase e. MK2, MAPK-activated protein kinase 2. JAK1, Janus kinase 1. AMPK, AMP-activated protein kinase.

(2) Inhibitory phosphorylation

The kinase activity of RIPK1 is tightly controlled at multiple levels to prevent spontaneous activation. Various post-translational modifications on RIPK1, such as ubiquitination and inhibitory phosphorylation, are intricately connected to keep RIPK1 kinase activity in check. For instance, in complex I, RIPK1 undergoes K63 ubiquitination by cIAP1/2 and M1 linear ubiquitination by LUBAC. These modifications stabilize Complex I, inhibiting its dissociation and formation of cell death-promoting complex II. In addition to activating the MAPK pathway and the NFκB pathway to activate gene expression that promotes cell survival and inflammation, TAK1 and IKK kinases further suppress cell death by performing inhibitory phosphorylations on RIPK1 to block its kinase activity (Figure 3). For instance, TAK1 activates MK2, which directly phosphorylates S320 and S335 of human RIPK1, or S321 and S336 of mouse RIPK1, to inhibit RIPK1 kinase activity and subsequent apoptosis or necroptosis⁷⁵⁻⁷⁷. Interestingly, TAK1 is also reported to directly phosphorylate mouse

RIPK1 at S321²⁹. In addition, TAK1 activates IKK α/β which in turn phosphorylates S25 in the kinase domain of RIPK1. Phosphorylation of S25 prevents ATP binding and inhibits RIPK1 kinase activation⁷⁸. Furthermore, TBK1/IKK ϵ phosphorylates T189 in the kinase domain to inhibit RIPK1 kinase activity^{32,79}. It is important to note that MK2 phosphorylates cytosolic RIPK1, while IKK α/β , TBK1/IKK ϵ and TAK1 phosphorylate ubiquitinated RIPK1 in complex I.

Recently, kinases outside of TNF pathway are also found to directly phosphorylate RIPK1 to inhibit its kinase activity and cell death. For example, glucose starvation activates AMPK (adenosine monophosphate-activated protein kinase) which phosphorylates S416 of human RIPK1 (or S415 of mouse RIPK1) to inhibit RIPK1 kinase activity and cell death⁸⁰.

In addition to serine/threonine-phosphorylation, tyrosine phosphorylation has also been found to inhibit RIPK1 activity. Studies have shown that JAK1 (Janus Kinase 1) and Src kinases phosphorylate Y384 of human RIPK1 (or Y383 of mouse RIPK1) to inhibit RIPK1 kinase activity and subsequent cell death⁸¹.

Inhibitory phosphorylation of RIPK1 plays a pivotal role in host defense against pathogens and modulates inflammatory responses. For example, the gram-negative bacterial pathogen *Yersinia* counters host defense by inhibiting NF κ B- and MAPK-mediated pro-inflammatory cytokines expression while promoting RIPK1 activation-dependent cell death⁸². Its effector protein acetyltransferase YopP/J elicits multiple functions in the process. First, it inactivates IKK α/β and TAK1 to block NF- κ B and MAPK activation⁸³. Second, it blocks the inhibitory phosphorylation of S25 of RIPK1 by IKK α/β to promote RIPK1-dependent macrophage cell death⁷⁸. Lastly, it inactivates MK2, preventing inhibitory phosphorylation of S321 and S335 on RIPK1, thereby activating RIPK1-dependent cell death^{75,76,84}. As a consequence, mice expressing the S25D-RIPK1 mutant fail to activate RIPK1-dependent cell death and are defective in defending against *Yersinia* infection, similar to the mice expressing the RIPK1 kinase-dead mutant K45A⁷⁸. In addition, inhibitors of TAK1, IKK α/β , IKK ϵ and MK2, the kinases responsible for the inhibitory phosphorylation of RIPK1, all exacerbate TNF-induced necroptosis and SIRS^{31,33,76,84,85}.

Together, the inhibitory phosphorylations by these kinases function as crucial checkpoints to prevent RIPK1 kinase activation and subsequent cell death. Dysregulation of any of these inhibitory phosphorylation events leads to elevated cell death and is frequently associated with inflammatory diseases.

Dephosphorylation of RIPK1

Protein phosphatases play a complementary role in regulating phosphorylation homeostasis. These enzymes are classified into three main families based on the sequence similarity of the catalytic domain and substrate specificity: PTPs (protein tyrosine phosphatases), PPPs (phosphoprotein phosphatases), and PPMs (protein phosphatase metal-dependent). PTPs specifically dephosphorylate phosphotyrosine residues, while PPPs and PPMs dephosphorylate phosphoserine and phosphothreonine residues. In addition, a subfamily of PTPs, called the dual specificity phosphatases, dephosphorylate all three phospho-amino acids. PPPs and PPMs differ in that PPMs require metal ions, such as magnesium or manganese, for their activity and function as single subunit enzymes, while PPPs require regulatory subunits⁸⁶.

PP1 (protein phosphatase 1) is an important subfamily of PPPs. Its catalytic subunits (PP1c), including PP1 α , PP1 β , and PP1 γ , are responsible for dephosphorylation of the majority phospho-serine and phospho-threonine sites in mammalian cells, regulating a broad range of cellular processes. Each PP1 catalytic subunit is obligatorily complexed with one or two regulatory subunits to form distinct PP1 holoenzymes. The regulatory subunits, also known as PP1-interacting proteins (PIPs) or regulatory interactors of protein phosphatase one (RIPPOs), determine substrate specificity by directing PP1c to the subcellular locations of its substrates and modulating its activity towards different substrates. There are approximately 200 validated PIPs, which assemble into more than 650 different PP1 holoenzymes in mammalian cells, enabling the dephosphorylation of diverse substrates⁸⁷.

While numerous kinases have been identified to phosphorylate RIPK1, only a limited number of phosphatases are found to dephosphorylate RIPK1 or RIPK3. For example, Ppm1b, a metal ion-dependent phosphatase, dephosphorylates and inactivates RIPK3 to prevent the recruitment of MLKL into the necrosome, thus inhibiting subsequent necroptosis. Moreover, *Ppm1b*^{-/-} mice exhibited heightened sensitivity to TNF-induced SIRS compared to WT mice, confirming its role in inhibiting necroptosis in vivo⁸⁸.

A sensitized CRISPR whole genome knockout screen revealed that PPP1R3G (protein phosphatase 1 regulator subunit 3G) is essential for necroptosis⁸⁹. Specifically, PPP1R3G forms a holoenzyme with PP1 γ to directly dephosphorylate the inhibitory phosphorylation sites of RIPK1, including S25, S320 and S335, thereby activating RIPK1-dependent apoptosis and necroptosis (Figure 4). An interesting note is that the holoenzyme does not remove the activating phosphorylation of S166 in vitro. In this context, upon treatment with TNF/Smac-mimetic/Z-VAD-FMK (T/S/Z), TRAF2 interacts with PPP1R3G to recruit the PPP1R3G/PP1 γ holoenzyme to complex I, where PP1 γ dephosphorylates the inhibitory phosphorylation sites of RIPK1, activating RIPK1 kinase. Loss of PPP1R3G leads to loss of RIPK1 autophosphorylation at S166 and subsequent failure to form complex IIb to induce cell death. Like many other PP1 regulatory subunits, PPP1R3G interacts with PP1 γ through a RVXF motif (X stands for any amino acids)⁹⁰. Mutation of RVQF in PPP1R3G to RAQA disrupts the interaction with PP1 γ . Importantly, the RAQA mutant fails to rescue RIPK1 activation and cell death in PPP1R3G knockout cells. Furthermore, prevention of RIPK1 inhibitory phosphorylations with p38 or IKK inhibitors or mutation of serine 25 of RIPK1 to alanine largely restores cell death in PPP1R3G-knockout cells. Finally, *Ppp1r3g*^{-/-} mice are protected from TNF-induced SIRS, confirming the important role of PPP1R3G in regulating apoptosis and necroptosis in vivo. Due to experimental sensitivity limitations, the authors were unable to determine if PPP1R3G/PP1 γ removes the inhibitory phosphorylation of T189. This warrants further analysis in the future. Additionally, it will be interesting to investigate if the PPP1R3G/PP1 γ holoenzyme removes inhibitory phosphorylation of S415.

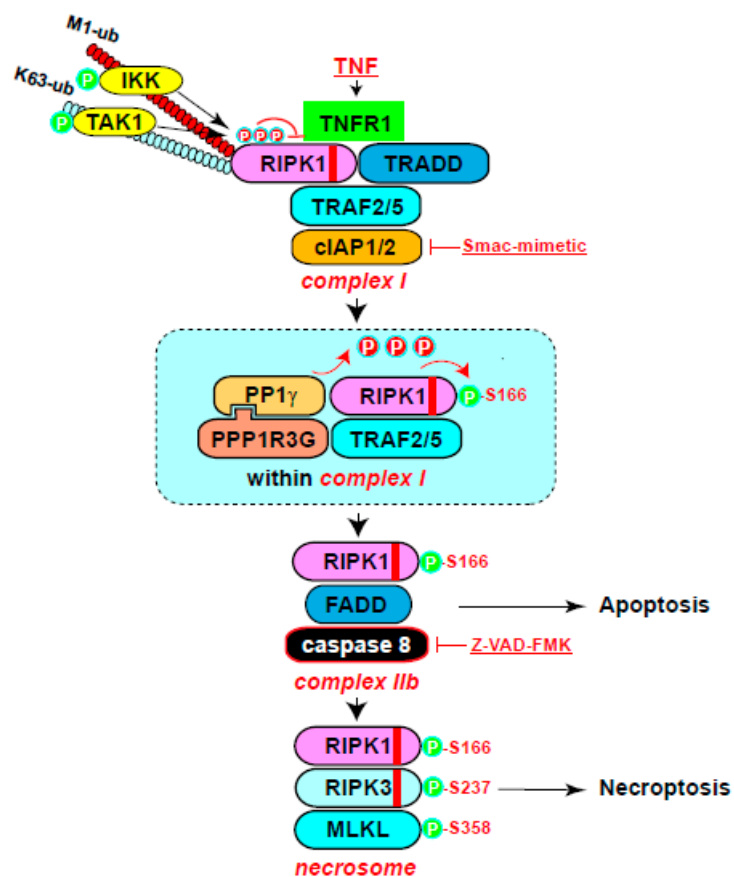

Figure 4. The PPP1R3G/PP1g holoenzyme removes the inhibitory phosphorylations of RIPK1 to activate RIPK1-dependent apoptosis and necroptosis. Inhibitory phosphorylations on RIPK1, catalyzed by multiple kinases, serve as important checkpoints for cell death activation. Following cell death induction, the PPP1R3G/PP1g holoenzyme is recruited to complex I to remove the inhibitory phosphorylations on RIPK1. This process enables RIPK1 autophosphorylation to activate its kinase activity and downstream cell death.

A recent study revealed that the PPP6C (protein phosphatase 6 catalytic subunit) is essential for necroptosis, identified through a CRISPR whole-genome knockout screen⁹¹. As previously reported⁹², PPP6C is recruited to complex I through TAB2, and dephosphorylates TAK1 to prevent inhibitory phosphorylations of RIPK1, thus activating TNF-induced necroptosis. Gastrointestinal tract-specific deletion of one allele of *Ppp6c* in mice could partially alleviate cecum damage caused by TNF-induced SIRS, confirming its role in necroptosis activation.

RIPK1 in Development

The scaffolding function, rather than kinase activity, of RIPK1 plays an important prosurvival role in regulating early postnatal lethality and inflammatory response by preventing apoptosis and necroptosis. Specifically, the death domain of RIPK1 binds the death domain of FADD to prevent FADD and Caspase-8-dependent apoptosis, while the RHIM domain of RIPK1 binds RHIM domains of RIPK3 and ZBP1, prevent their hyperactivation-induced necroptosis. For example, genetic deletion of RIPK1 in mice causes postnatal lethality⁹³. While double knockout of RIPK3, Caspase-8 or FADD along with RIPK1 only marginally prolonged survival⁹⁴⁻⁹⁶, triple knockout of RIPK1, RIPK3 and either Caspase-8 or FADD rescued RIPK1-deficient mice, allowing them to survive weaning and mature normally^{97,98}. The RHIM domain of RIPK1 inhibits ZBP1-RIPK3-MLKL-mediated necroptosis, crucial for preventing late embryonic lethality and adult skin inflammation^{99,100}. Moreover, RIPK1 is essential for maintaining the survival of intestinal epithelial cells (IECs) by blocking apoptosis and necroptosis¹⁰¹. Additionally, mice harboring RIPK1 kinase-dead knock-in mutants, including D138N and K45A, survive to adulthood with no gross or histological abnormalities, indicating that RIPK1 kinase activity is dispensable for survival^{37,38}.

RIPK1-Mediated Inflammatory Diseases

Many human inflammatory and neurodegenerative diseases have been found to be associated with abnormal RIPK1 expression or activity. Reports of genes mutations or non-genetic factors that affect RIPK1 activity are accumulating, highlighting the importance of RIPK1 regulation in human diseases.

Reduced RIPK1 expression can lead to various human diseases, largely due to the hyperactivation of RIPK3, ZBP1 and Caspase-8. As discussed previously, RIPK1 neutralizes RIPK3 and ZBP1 through RHIM domain interaction under normal conditions, and loss of RIPK1 leads to overactivation of ZBP1 and RIPK3, resulting in excessive necroptosis and systemic inflammation. At the meantime, RIPK1 inhibits FADD/Caspase-8-mediated apoptosis through death domain interaction during development, and loss of RIPK1 leads to excessive apoptosis. In humans, rare homozygous loss of function (LoF) mutations in RIPK1, including missense, nonsense and frameshift mutations, cause combined immunodeficiency and inflammatory bowel disease (IBD). Many of these patients also suffer from lymphopenia, recurrent infections, and arthritis¹⁰²⁻¹⁰⁵.

Conversely, elevated RIPK1 activity is also implicated in various human diseases due to heightened inflammation and cell death. For instance, rare mutations in RIPK1, such as D324N, D324H and D324Y at the Caspase-8 recognition site LQLD, block Caspase-8-mediated cleavage of RIPK1, resulting in an autosomal dominant autoinflammatory disease, characterized by recurrent fevers and lymphadenopathy¹⁰⁶⁻¹⁰⁸. Patients with these variants often have increased pro-inflammatory cytokines and chemokines, such as IL-6, TNF and CXCL2/3, and their peripheral blood mononuclear cells are hypersensitive to RIPK1 activation-dependent apoptosis and necroptosis induced by TNF α .

Furthermore, mutations in other genes that result in hyperactivation of RIPK1 kinase activity also lead to human diseases. For instance, monogenic mutations in genes like *IKBKG* (encoding NEMO), *TNIP1* (encoding ABIN1), *TNFAIP3* (encoding A20), and members of the *LUBAC* complex, have been linked to auto-immune and inflammatory disorders, such as inflammatory bowel disease, psoriasis, rheumatoid arthritis and multiple sclerosis¹⁰⁹⁻¹¹². Interestingly, these genes are also involved in regulating NF κ B signaling¹¹³. Animal model studies demonstrate that genetic or pharmacological inhibition of RIPK1 kinase activity can alleviate pathological symptoms, indicating that the pathogenesis resulting from these mutations may be driven more by dysregulated RIPK1-dependent cell death and inflammatory mechanisms rather than failure to activate NF κ B^{35,60}.

Several chronic neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS), Alzheimer disease (AD) and Parkinson disease (PD), are also linked to increased activation of RIPK1¹¹⁴⁻¹¹⁶. For example, mutations in the *optineurin* (*OPTN*) gene have been implicated in human ALS. In mouse models, loss of *OPTN* leads to elevated RIPK1 activity, as well as downstream RIPK3 and MLKL activation, resulting in axon degeneration, which is partially rescued by *Ripk3* loss-of-function or treatment with a RIPK1 inhibitor necrostatin¹¹⁴. Furthermore, aging-induced reduction of TAK1 expression combined with *TBK1* mutations promotes the onset of neurodegenerative diseases, including ALS and frontotemporal dementia (FTD). This is mainly attributed to the hyperactivation of RIPK1, due to decreased inhibitory phosphorylations resulting from reduced activity of TAK1 and TBK1. Importantly, the ALS/FTD phenotype is partially rescued by a single allele of kinase-dead RIPK1³².

Therapeutic Perspectives

Elevated RIPK1 activity is associated with numerous human diseases, making it a crucial target for therapeutic interventions. In theory, RIPK1 kinase inhibitors will prevent RIPK1 hyperactivation-induced inflammatory diseases, while preserving RIPK1 scaffold function to maintain its basal inhibition on RIPK3, ZBP1 and FADD/Caspase-8, thus averting unwanted necroptosis or apoptosis. Indeed, in mouse models, RIPK1 inhibitors have been shown to prevent or alleviate clinical symptoms of various diseases, including SIRS, ischemia-induced tissue injury, neurodegeneration, bacterial and viral infection². Currently, numerous RIPK1 inhibitors are in different phases of clinical trials for a spectrum of human inflammatory diseases, ranging from rheumatoid arthritis, cutaneous lupus erythematosus, ulcerative colitis, SARS-CoV-2 infection, to Alzheimer's disease and ALS¹¹⁷⁻¹¹⁹ (ClinicalTrials.gov). While many of these inhibitors have passed the phase I safety test, none has progressed to phase III trial yet.

Considering the diverse functions of RIPK1 and the uncertain outcomes of the clinical trials involving RIPK1 inhibitors, there is a pressing need to identify novel targets for specifically inhibiting its cell death-promoting activity. Considering the pivotal role of PPP1R3G/PP1 γ in removing inhibitory phosphorylation sites on RIPK1, it emerges as a promising alternative therapeutic target. Notably, PPP1R3G interacts with PP1 γ through a short RVQF motif, presenting a unique opportunity to develop short peptide-mimetics that disrupt PPP1R3G and PP1 γ interaction, blocking RIPK1-dependent apoptosis and necroptosis. The same approach has been successfully employed in designing the Smac-mimetics, which mimics the four-residue AVPI sequence in the SMAC (Second Mitochondria-derived Activator of Caspases) protein. These mimetics specifically block the interaction between SMAC and IAPs (Inhibitor of Apoptosis Proteins), thereby inducing apoptosis^{27,28,120}. Unlike RIPK1 inhibitors, these PPP1R3G/PP1 γ interaction inhibitors will maintain the inhibitory phosphorylation sites on RIPK1, preventing its hyperactivation, while not altering RIPK1 scaffold function, thereby preserving its other functions. At the same time, these inhibitors would have minimal impact on the phosphatase activity of PP1 γ , thus maintaining its other vital functions. This innovative approach holds potential for therapeutic interventions targeting inflammatory diseases associated with heightened RIPK1 activity, while minimizing any adverse effects on cellular homeostasis.

Conclusion and Future Perspectives

The critical role of RIPK1 in modulating both cell survival and cell death underscores the necessity for tight regulation of its activity. In addition to phosphorylation, other post-translational modifications like ubiquitination and glycosylation also significantly impact RIPK1's scaffolding function and kinase activity. Yet, the intricate interplay among these modifications and how they collectively regulate RIPK1 function still require further elucidation. A comprehensive understanding of this complex regulatory network holds promise for the development of more effective treatments targeting RIPK1-related conditions in the future.
