Abstract: With increasing research focus on industrial anomaly detection, numerous methods have emerged in this domain. Notably, memory bank-based approaches, coupled with k distance metrics, have demonstrated remarkable performance in anomaly detection (AD) and anomaly segmentation (AS). However, upon examination of the Back to the Feature (BTF) method applied to the MVTec-3D AD dataset, it was observed that while it exhibited exceptional segmentation performance, its detection performance was lacking. To address this discrepancy, this study improves the implementation of BTF, especially the improvement of the anomaly score metric. It hypothesizes that when calculating the anomaly score for each sample, only the k -nearest neighbors within the same cluster should be considered. For ease of algorithm implementation, this assumption is distilled into the proposition that AD and AS tasks necessitate different k values in k distance metrics. Consequently, the paper introduces the BTM method, which utilizes distinct distance metrics for AD and AS tasks. This innovative approach yields superior AD and AS performance (I-AUROC 93.0%, AURPO 96.9%, P-AUROC 99.5%), representing a substantial enhancement over the BTF method (I-AUROC 5.7% \uparrow , AURPO 0.5% \uparrow , P-AUROC 0.2% \uparrow).

Keywords: image anomaly detection; defect detection; industrial manufacturing; distance metrics; anomaly score distribution

1. Introduction

Anomaly detection (AD) aims at finding instances that diverge from the "normal" data in the general sense[1–4]. Meanwhile, anomaly segmentation (AS) looks into specific anomalous instances and precisely delineates the abnormal regions, such as identifying the locations of abnormal pixels. The combined field of anomaly detection and segmentation (AD&S) plays a critical role in various applications, including industrial inspection, security surveillance, and medical image analysis [3,5,6].

1.1. 2D Industrial Anomaly Detection

When 2D industrial anomaly detection becomes increasingly emphasized, datasets such as MVTec AD [5,6], BTAD [7], MTD [8], and MVTec LOCO AD [9] have been successively introduced. MVTec AD includes various industrial objects and materials with normal and anomalous samples, BTAD focuses on transparent bottle anomalies, MTD targets defects in magnetic tiles, and MVTec LOCOAD evaluates methods under logical constraints and complex scenes. This has stimulated the development of industrial AD&S and facilitated the proposal of many novel AD&S methods. We categorize these methods into three main types:

1. **Supervised Learning:** These algorithms treat anomaly detection as an imbalanced binary classification problem. This approach suffers from the scarcity of abnormal samples and the high cost of labeling. To deal with the problems, various methods were proposed to generate anomalous samples so as to alleviate the labeling cost. For example, CutPaste[10] and DRAEM[11] manually construct anomalous samples; SimpleNet[12] samples anomalous features near positive sample features; NSA[13] and GRAD[14] synthesize anomalous samples based on normal samples. Despite the diversity of anomaly generation methods, they consistently fail to address the underlying issue of discrepancies between the distributions of generated and real data [15–17].

2. **Unsupervised Learning:** These algorithms operate under the assumption that the data follow a normal distribution. For example, SROC [18] and SRR [19] rely on this assumption to identify and remove minor anomalies from the normal data. When combined with semi-supervised learning techniques, these algorithms achieve enhanced performance.
3. **Semi-supervised Learning:** The concentration assumption, which supposes the normal data are usually bounded if the features extracted are good enough, is commonly used when designing semi-supervised learning AD&S methods. These algorithms require only labels for normal data and assume boundaries in the normal data distribution for anomaly detection. Examples include: Autoencoder-based [20–22], GAN-based [20,23–25], Flow-based[26–30], and SVDD-based [31–33]. Some memory bank-based methods (MBBM) [16,17,34–37] that combine pre-trained features from deep neural networks with traditional semi-supervised algorithms have achieved particularly outstanding results and also possess strong interpretability. In rough chronological order, we summarize the main related algorithms as follows:
 - (a) DN2 [34] was the first to use k -nearest neighbors (k NN) with deep pre-trained features for AD task, and introduces Group Anomaly Detection (GAD) [38]. After that, some works [16,17] fit Gaussian distributions to deep pre-trained features for anomaly scoring using Mahalanobis distance.
 - (b) SPADE, building on DN2, [35] employs Feature Pyramid Matching to achieve image AD&S.
 - (c) PaDiM [36] models pre-trained feature patches with Gaussian distributions for better AD&S performance.
 - (d) Panda [33] sets subtasks based on pre-trained features for model tuning, to achieve better feature extraction and improve model performance.
 - (e) PatchCore [37] and ReConPatch [39] have achieved excellent performance by utilizing downsampled pre-trained feature sets from the k NN method. They have consistently held top positions on the performance leaderboard for an extended period.

1.2. 3D Industrial Anomaly Detection

To fill the gap in the 3D AD&S domain, the MVTec-3D AD [40] dataset along with its corresponding baseline algorithms and performance metrics were released to the public, which introduced new opportunities and challenges to industrial AD&S. In subsequent research, various novel methods have been developed and achieved notable results. These include methods based on teacher-student networks such as 3D-ST [41] and AST [42], methods leveraging the PatchCore scoring function like (Back to the Features) BTF [43] and M3DM [44], and methods focused on constructing anomalies such as 3DSR [45]. Additionally, approaches that utilize Neural Implicit Functions and pre-trained models, exemplified by Shape-Guided [46], have been introduced. These studies primarily aim to design new methods for 3D feature extraction and feature integration.

In the MVTec-3D AD dataset, it was observed that BTF achieved significant performance in terms of AS, but lagged in AD performance. Upon further investigation, it was found that methods such as ReConPatch, BTF, and M3DM perform anomaly scoring calculations based on the PatchCore method. These algorithms differ significantly from the initially proposed image domain anomaly scoring algorithm based on k NN [34] and the traditional k NN classification algorithm [47]. The papers lacked specific discussion when introducing these differences. In this paper, the distance measures involved in these algorithms are compared and analyzed, and their advantages and disadvantages are pointed out. According to these advantages and disadvantages, combined with our improvement of the existing MBBM method, we propose a method that uses different anomaly scores in the AD and AS phases, respectively.

1.3. Evaluation Metrics

In this study, we use several key evaluation metrics to assess the performance of our proposed method, including I-AUROC[5,6], P-AUROC[5,6], and AUPRO[6,43,44].

- **I-AUROC (Instance-based AUROC):** This metric measures the AUROC at the instance level, which is crucial for image anomaly detection. It calculates the AUROC value for each image or object, providing an evaluation of the model's performance on individual instances. The formula is:

$$I\text{-AUROC} = \frac{1}{N} \sum_{i=1}^N \text{AUROC}(y_i, \hat{y}_i) \quad (1)$$

where N is the number of instances, y_i is the true label of instance i , and \hat{y}_i is the predicted probability for instance i .

- **P-AUROC (Pixel-based AUROC):** This metric calculates the AUROC at the pixel level, which is essential for evaluating the performance of anomaly segmentation tasks. It considers the predictions and true labels of each pixel within the images. The formula is:

$$P\text{-AUROC} = \frac{1}{M} \sum_{j=1}^M \text{AUROC}(y_j, \hat{y}_j) \quad (2)$$

where M is the total number of pixels, y_j is the true label of pixel j , and \hat{y}_j is the predicted probability for pixel j .

- **PRO (Per-region Overlap):** This metric evaluates the overlap between predicted anomaly regions and ground truth regions, specifically for anomaly segmentation. The formula is:

$$PRO = \frac{1}{K} \sum_{k=1}^K \frac{|P_k \cap T_k|}{|P_k \cup T_k|} \quad (3)$$

where K is the number of anomaly regions, P_k is the predicted k -th anomaly region, and T_k is the ground truth k -th anomaly region. PRO considers the size and location of anomaly regions, making it useful for evaluating segmentation performance.

- **AUPRO (Area Under the PRO Curve):** This metric evaluates the performance of anomaly segmentation by calculating the area under the PRO curve. PRO measures the overlap between predicted and ground truth anomaly regions. The formula is:

$$AUPRO = \int_0^1 PRO(T) dT \quad (4)$$

where T represents different thresholds, and $PRO(T)$ is the PRO score at threshold T . AUPRO is similar to AUROC but is specifically designed for anomaly segmentation tasks, summarizing the model's performance across different thresholds.

In the field of industrial anomaly detection, our work primarily focuses on the I-AUROC as the key performance metric, with AUPRO as the secondary metric. For practical applications, especially when emphasizing model performance at lower false positive rates (FPR), we often set an upper limit for AUPRO integration. By choosing 0.3 as the upper limit, we calculate the area under the PRO curve only for FPR between 0% and 30%.

1.4. Contributions and Paper Organization

The key contributions of this work include:

1. **Methodological Clarification (PatchCore and BTF):** We compare and analyze the theoretical framework and official implementation of PatchCore and BTF, then make improvements to some details found in the paper or code, while clarifying the framework of BTM.
2. **Distance Metric Analysis:** We visualized and analyzed the distance measure in the anomaly scoring algorithm, providing initial insights into its strengths and weaknesses. Based on these analyses, we also propose some assumptions.

3. **Method Proposed:** On the basis of BTF, a method named Back to the Metrics (BTM) is proposed in Section 2.1, which achieves the performance improvement of (I-AUROC 5.7% ↑, AURPO 0.5% ↑, and P-AUROC 0.2% ↑). It is also competitive against other leading methods.

This paper is divided into three parts:

1. Section 2 optimizes the nearest neighbor feature fusion, feature alignment and distance metric based on BTF, and proposes the BTM method. Then, the basis of modification is introduced, including a summary of the framework of MBBM method, and an analysis of the implementation details of MBBM (anomaly score calculation, feature fusion and downsampling method).
2. Section 3 first provides comprehensive information on the datasets used, code implementation details, and parameters used. On this basis, it then compares the performance of the proposed method in section 2 using real datasets.
3. Section 4 summarizes the conclusions drawn in this work and explores future research directions.

2. Methodology

2.1. Back to the Metric

2.1.1. Framework

This section describes the general framework of BTM method through the summary of MBBM method.

In BTM, we have followed the traditional framework of MBBM framework illustrated in Figure 1. Specifically, Figure 1a is dedicated to introducing MBBM. For methods focused solely on anomaly detection (AD), it can be elucidated that the Patch Features Extractor (PFE) extracts only one feature for each sample. In other words, such methods treat the entire image as a single patch. Figure 1b shows the feature extraction process of BTM method on MVTec-3D AD dataset. The process depicted is consistent with BTF, with variations noted in Section 3.3 and Section 2.1.2.

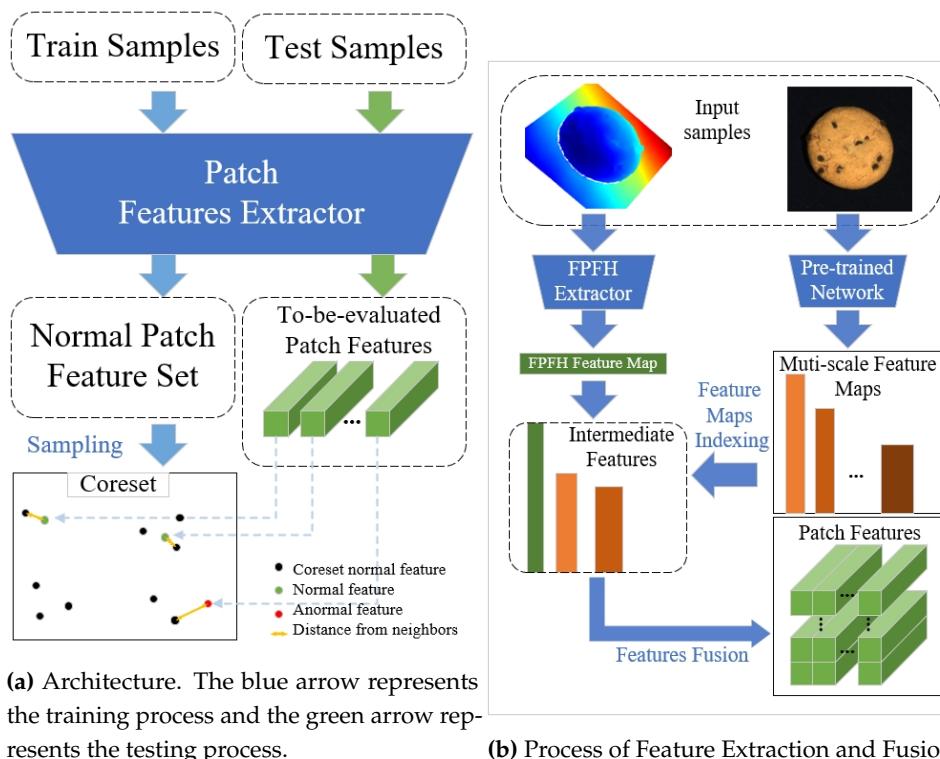

Figure 1. (a) The Architecture of the Back to the Metrics(BTM). (b) Process of Feature Extraction and Fusion with Fast Point Feature Histograms (FPFH) and Pre-trained Network

2.1.2. Optimization

On the framework shown in Figure 1, we opt to use k NN Squared Distance Mean Metrics as the anomaly score calculation function for AS tasks, and employ nearest neighbor Metrics to compute image-level anomaly scores. We term this approach BTM and conduct AD&S experiments on the MVTec-3D AD dataset.

Building upon BTF, we referenced DN2's work on GAD and, considering the alignment requirements between images and features, utilized a mean convolution kernel with kernel-size=3, stride=1, and padding=1 to fuse neighboring features. For the sake of logical correctness and code parallelism, we replaced the elliptical Gaussian blur kernel used in computing AS anomaly scores with a Gaussian blur kernel of kernel-size=15 and sigma=(4,4), directly applicable to tensors. We'll get into the details of why these changes were made in a later section.

2.2. The Structure of Memory Bank Based Methods(MBBM)

2.2.1. Anomaly Score Metrics

Traditional k NN algorithm is a classification algorithm based on similarity metrics. It determines the category of a new sample by selecting k NN to vote, where k is usually chosen as an odd number to avoid ties during the voting process[47]. In semi-supervised anomaly detection, anomalous samples do not appear in the training set. In contrast, the MBBM considers the influence of multiple different normal samples in the anomaly scoring function through techniques like re-weighting.

DN2 is the first model to introduce a k NN-based method in industrial image anomaly detection, scoring image anomalies using Equation 5.

$$s = d(x) = \frac{1}{k} \sum_{f \in \mathcal{N}_k(f_x)} \|f - f_x\|_2 \quad (5)$$

The symbol $\mathcal{N}_k(f_x)$ represents the set of k nearest feature vectors to f_x within the training set F_{train} . The anomaly score s of the test image is denoted by the distance function $d(x)$, which is the average sum of squared Euclidean distances between the feature vector f_x and the feature vectors f in its k NN $\mathcal{N}_k(f_x)$. The rule with $k = 1$ is commonly referred to as the nearest-neighbor rule.[47]

Work such as SPADE further extends DN2 to AS tasks. For an image sample that is divided into I rows and J columns: $f_{i,j}$ represents the feature extracted from the patch at the i th row and j th column, and

$$F = \{f_{i,j} \mid 0 \leq i < I, 0 \leq j < J\}$$

represents the set of features for the entire image; let $s_{i,j}$ represent the anomaly score of the patch at the i th row and j th column; let \mathcal{M} represent the cores of features obtained by applying a greedy algorithm for subsampling on the set of patch features from all images in the training set; let $\mathcal{N}_k(f_y)$ represent the set of k nearest features to f_y in \mathcal{M} .

$$s_{i,j} = \frac{1}{k} \sum_{f \in \mathcal{N}_k(f_{i,j})} \|f - f_{i,j}\|_2 \quad (6)$$

For each image, PatchCore's official code uses Equation 6 for AS anomaly score calculation, where $k = 1$ in the paper, which can be represented by Equation 7.

$$s_{i,j} = \min_{m \in \mathcal{M}} \|m - f_{i,j}\|_2 \quad (7)$$

PatchCore defines the maximum distance score s^* of a test image, which can be expressed as Equation 8 or more closely to the original text as Appendix A (less rigorous). Here, f_{i^*,j^*} is the feature in the test image with the highest anomaly score, and m^* is the feature in the core set \mathcal{M} that is nearest to f_{i^*,j^*} .

$$s^* = \max_{0 \leq i < I, 0 \leq j < J} s_{i,j} \quad (8)$$

It is noteworthy that, in conjunction with the understanding of Equation 7 and Equation 8, we propose that the terms m^* and f_{i^*,j^*} in Equation A1 and Equation A2 need to be redefined as shown in Equation 9. Here, $m_{i,j}$ represents the nearest neighbor of f_{i^*,j^*} within \mathcal{M} , and S_{fm} denotes the set composed of tuples, each consisting of all patch features from an image and their respective nearest neighbors in \mathcal{M} .

$$\begin{aligned} m_{i,j} &= \arg \min_{m \in \mathcal{M}} \|m - f_{i,j}\|_2 \\ S_{fm} &= \{(f_{i,j}, m_{i,j}) \mid 0 \leq i < I, 0 \leq j < J\} \\ (f_{i^*,j^*}, m^*) &= \arg \max_{(f_{i,j}, m_{i,j}) \in S_{fm}} \|m_{i,j} - f_{i,j}\|_2 \end{aligned} \quad (9)$$

$$w = \left(1 - \frac{\exp(\|f_{i^*,j^*} - m^*\|_2)}{\sum_{m \in \mathcal{N}_k(m^*)} \exp(\|f_{i^*,j^*} - m\|_2)} \right) \quad (10)$$

$$s = w \cdot s^* \quad (11)$$

To make the image anomaly scoring results more robust [37], PatchCore employs the weights w from Equation 10 to reweight s^* as the anomaly score, as shown in Equation 11. BTF and M3DM both implemented Equation 10 in their code, but M3DM employed complex methods such as reweighting and One-Class Support Vector Machines for anomaly score re-calculation.

$$\begin{aligned} \alpha_1 &= \frac{\exp(\|f_{i^*,j^*} - m^*\|_2)}{\sum_{m \in \mathcal{N}_k(m^*)} \exp(\|f_{i^*,j^*} - m\|_2)} \\ \alpha_2 &= \sum_{m \in \mathcal{N}_k(m^*)} \exp(\|f_{i^*,j^*} - m\|_2) \\ &= \sum_{m \in \mathcal{N}_k(m^*)} \exp(\sqrt{f_{i^*,j^*}^T f_{i^*,j^*} - 2f_{i^*,j^*}^T m + m^T m}) \\ &= \sum_{m \in \mathcal{N}_k(m^*)} \exp(\sqrt{\|f_{i^*,j^*}\|_2^2 - 2f_{i^*,j^*}^T m + \|m\|_2^2}) \end{aligned} \quad (12)$$

To facilitate further analysis, we define partial component factors (or terms) α_1 and α_2 of the variable w as shown in Equation 12. The exponential function $\exp(\cdot)$ and the square root function $\sqrt{\cdot}$ are monotonically increasing and therefore not specifically considered.

In the analysis of α_2 , the terms $\|f_{i^*,j^*}\|_2^2$, $\|m\|_2^2$, and $f_{i^*,j^*}^T m$ can have adverse effects on the contour plots of the anomaly scores. These factors can lead to distortions in the visualization, making it challenging to accurately interpret the results. The impact of these terms on the anomaly contour plots is illustrated in Figures 4–6.

In summary, the officially released PatchCore-derived methods currently primarily utilize the anomaly scores Equation 6 and Equation 7 for the AS task, and Equation 6, Equation 7, and Equation 9 for the AD task.

2.2.2. Feature Fusion

In pure image anomaly detection (AD) tasks, the issue of feature fusion is not inherently involved. However, DN2 explored it as a GAD problem: as shown in Figure 2, DN2 compared three methods of feature fusion—concatenate, max, and mean—and found that using mean for feature fusion combined

with the *k*NN anomaly score calculation algorithm resulted in the best ROCAUC performance. In contrast, the performance of the concatenate method in terms of ROCAUC first increased and then decreased with the enlargement of the group size. This experiment offers some inspiration for feature fusion methods in subsequent work.

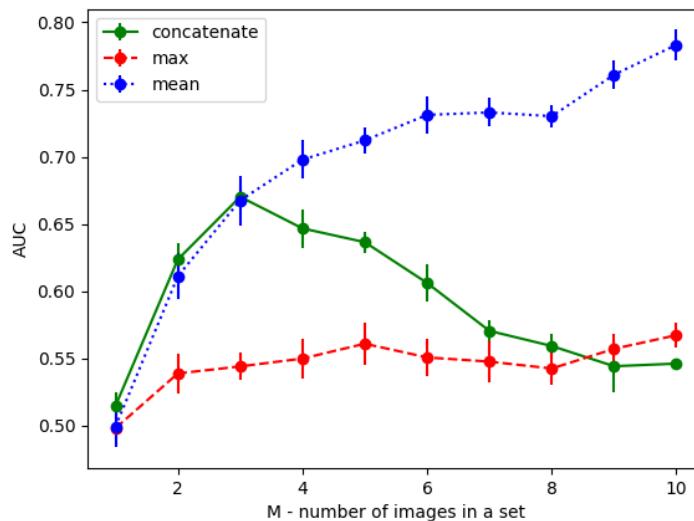

Figure 2. ¹Performance comparison of anomaly detection methods using feature concatenation, max pooling, and mean pooling with varying numbers of images per group[34].

In the anomaly score (AS) of methods derived from PatchCore, two variants of feature fusion appear: 1) On the MVTec-3D AD dataset, the PatchCore code upsamples the high-level feature map to the same resolution as the low-level features using bilinear interpolation, then maps different levels to the same dimension (e.g., hyperparameter 1024), concatenates them together, and finally maps them to a feature vector of a specific dimension. 2) On 3D datasets, BTF and M3DM first use the mean method to perform domain feature fusion for different layer features (including RBB multi-scale features and geometric features), then the high-level feature map is upsampled to the same resolution as the low-level features using bilinear interpolation, and finally, the features from all layers are concatenated together to generate a feature vector.

Overall, the fusion of features from the same modality, such as the fusion of features from the same spatial domain, can be approached as a GAD problem, where using the mean method can yield better performance, especially when many features are involved. On the other hand, for the fusion of features from different modalities, including different scales and different characteristics, concatenation is a more common choice. More sophisticated and complex feature fusion techniques, such as those used by M3DM, are beyond the scope of this discussion.

Referring to DN2's work on GAD, in BTM we make the mean convolution kernel of size 3 and step 1 perform neighbor feature fusion, which is the same as in BTF. The difference is, given the feature alignment, we add a padding of size 1 to the convolution kernel. For features other than nearest neighbor features, we simply use concatenate as a feature fusion method.

2.2.3. The Iterative Greedy Approximation Algorithm

Both PatchCore and BTF utilize the Iterative Greedy Approximation (IGA) algorithm [48] to subsample the memory bank. IGA significantly addresses the issue of overemphasis on outlier samples in both active learning and anomaly detection scenarios. This method ensures the coverage,

¹ Image reprinted with permission from Yedid Hoshen, for academic use only. (arXiv preprint arXiv:2002.10445; published by arXiv, 2020.)

representativeness, and information complexity of the coresset samples. However, it is worth noting that in active learning, the normalcy of outliers is not a primary concern, whereas in anomaly detection, it is important.

The IGA algorithm tends to collect samples at the edges of sample clusters, typically high-frequency samples around low-frequency regions. Based on this characteristic of the IGA algorithm, we have the following assumptions:

Assumption 1. *If there are abnormal samples in the training set, they are likely to be captured by IGA and become outliers (considered normal) in the core set.*

Assumption 2. *The low-frequency areas near high-frequency features (The boundary of the sample cluster), data points are likely to be outliers and should receive higher anomaly scores.*

2.3. Visualization Analysis of Different Metrics

In MBBM, the interaction between the anomaly score calculation function and feature engineering ultimately affects the calculation of anomaly scores. In existing research on image anomaly detection, the evaluation of anomaly score calculation functions is typically manifested as performance metrics on specific datasets. However, this is far from sufficient [49]. Considering the inherent flaws of real datasets and the significant impact of complex variable interactions on results, we simulate sample distributions in two-dimensional space to facilitate the visual analysis of anomaly score functions.

$$\begin{aligned} v_x &= \left\{ x \in \mathbb{R} \mid x = x_0 + 0.005n, n \in \mathbb{N}, 0 \leq n < \frac{x_1 - x_0}{0.005} \right\} \\ v_y &= \left\{ y \in \mathbb{R} \mid y = y_0 + 0.005n, n \in \mathbb{N}, 0 \leq n < \frac{y_1 - y_0}{0.005} \right\} \\ \text{Grid} &= v \times v, \quad \text{Grid} \in \mathbb{R}^{\lfloor (x_1 - x_0)(y_1 - y_0) \rfloor / 0.00005 \times 2} \end{aligned} \quad (13)$$

As shown in Equation 13, this study uses v_x and v_y to respectively denote one-dimensional grid vectors along the x and y axes within the visualization region ($x_0 < x < x_1, y_0 < y < y_1$), and employs Grid to represent the two-dimensional spatial vector for visualization. The values x_0, x_1, y_0 , and y_1 are manually input to define the visualization range. We employ random sampling within the Grid to generate a core set $\in \mathbb{R}^{n \times 2}$, and subsequently visualize the gradient of anomaly scores within the Grid range.

The set $\text{dists} = \{(\|x - c\|_2) \mid x \in \text{Grid}, c \in \text{coreset}\}$ denotes the Euclidean distance between the points (x, y) in Grid and points c in coreset . By substituting dists into the corresponding formula, one can obtain the anomaly score or anomaly score weights Z , which are ultimately used to draw contours. Both dists and the anomaly scores can be obtained through parallel computation.

2.3.1. k -Nearest Neighbor Squared Distance Mean

When $k = 1$, as shown in Figure 3a, the algorithm ensures adequate sample coverage and representativeness. As k increases, as illustrated in Figure 3, the coverage and representativeness of outlier points significantly decrease, while the robustness of the anomaly score calculation function to outlier points slightly improves.

Larger k values can increase the robustness of the model and reduce the influence of outliers, but at the expense of sample representativeness and coverage. When $k > 1$, we see a score distribution that conforms to Assumption 2. When the number of test samples is large enough and most of them are normal, it is a good choice to increase the k value appropriately to increase the robustness of the abnormal samples that may be introduced by Assumption 1. This fits the scenario of the AS task.

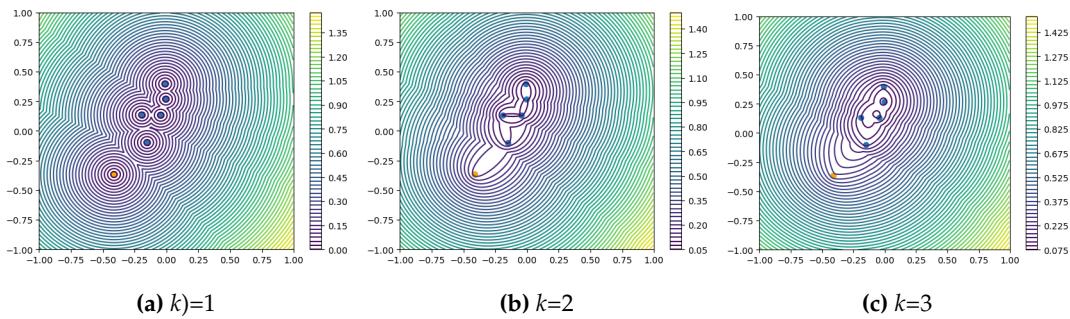

Figure 3. Contour plots of Equation 6 for anomaly scores under simulated coresets with different values of k . Orange dots represent outliers.

However, as we can see from the graph 3b, when k increases, there will be many "gullies" in the gradient plot of the abnormal fraction function. These "gullies" exist regardless of whether the outliers are normal or abnormal. Samples located in gullies will be assigned the same anomaly scores, losing their ability to distinguish anomalies. When Patch Core and BTF process AD tasks, the patch with the highest anomaly score plays a decisive role. In cases where a known sample is likely to be an anomaly (has a high probability of not being affected by outliers and reducing the anomaly score), the presence of these gullies is not conducive to the recall of anomalies.

To sum up, MBBM uses k -nearest Neighbor Squared Distance Mean to measure the k value that may be needed for processing AS tasks. It is best to keep $k=1$ when processing AD tasks.

2.3.2. PatchCore Anomaly Score Calculation Function

The function composition of α_1 resembles Softmax. As shown in Figure 4, α_1 has larger values at the boundaries of the sample coverage area. As k increases, the maximum value of α_1 first decreases rapidly and then decreases slowly, approximately inversely proportional to k . Combining Equation 11 and Equation 12, we can observe that as k increases, the weight w tends to approach 1, and the influence of distance variance on the final anomaly score decreases.

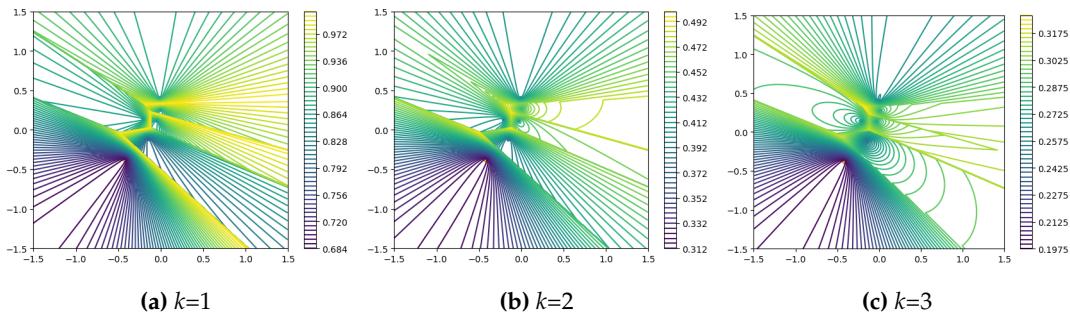

Figure 4. Contour plots of the α_1 of Equation 12 under simulated coresets with different values of k . Orange dots represent outliers.

Figures 5 and 6 illustrate the behavior of s and w in Equation 11. w increases with the increase of k , while its factor α_1 decreases significantly. Except for Figure 5a, which exhibits a bizarre distribution of anomalies due to excessive influence from α_1 , assuming a randomly distributed sample set, both Figure 5a and Figure 5a are relatively reasonable: they conform to Assumption 2. If the outliers in the normal samples are marginal samples of this cluster, the gradient of anomaly scores on the outlier side is larger.

In other words, w induces a subtle merging phenomenon in the distribution of anomaly scores for the k nearest neighbors of each point. This has adverse effects on the distribution of anomaly scores for clusters with a size less than or equal to k .

As shown in Figure 7b, when $k = 2$, the distribution of anomaly scores around the cluster composed of 3 sample points on the right side of the image does not exhibit significant inward shifting,

forming a closed whole. Around the cluster composed of 2 sample points in the middle, a slight phenomenon of shifting towards the right side appears. While around the cluster composed of 1 sample point on the left side, there is a clear tendency for merging towards the right side. All clusters shown in Figure 7b exhibit slight merging phenomena. These merging or shifting phenomena are inconsistent with our assumptions.

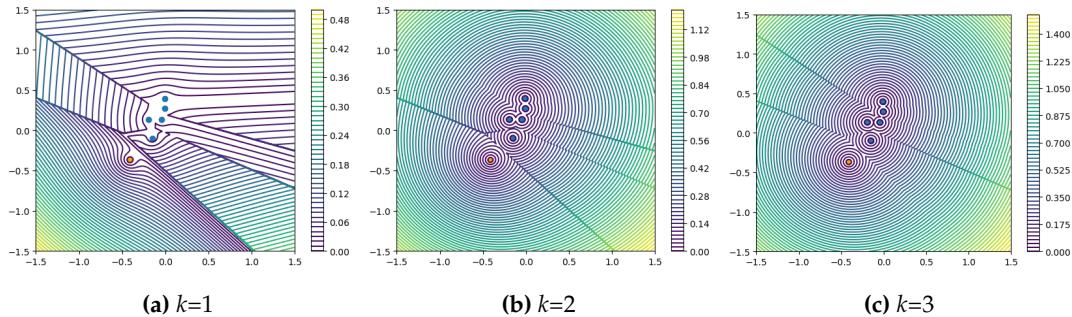

Figure 5. Contour plots of Equation 11 for anomaly scores under simulated coresets with different values of k . Orange dots represent outliers.

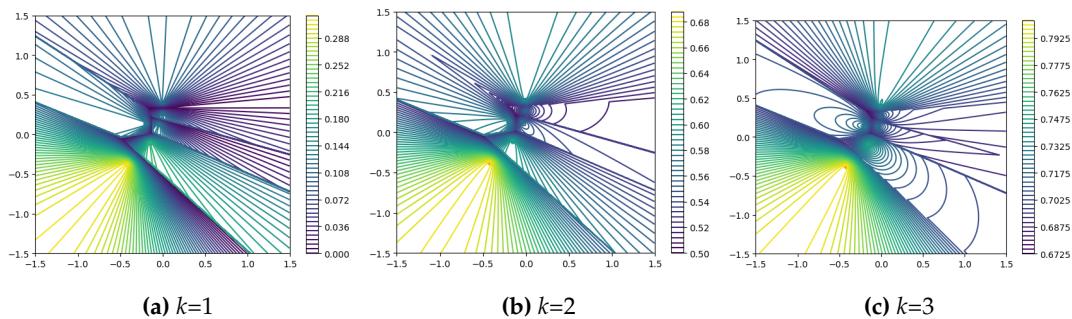

Figure 6. Contour plots of the weight values of Equation 11 under simulated coresets with different values of k . Orange dots represent outliers.

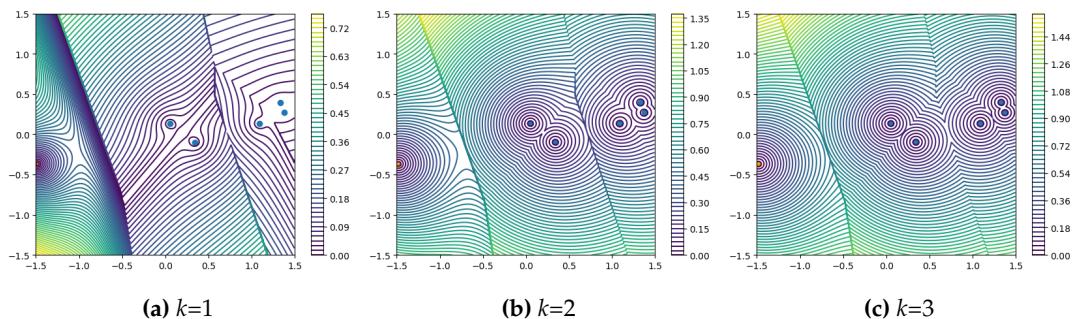

Figure 7. Enlarge the abscissa of the six samples in the coresset in Figure 5 by a factor of 7, dividing them into three clusters consisting of 1, 2, and 3 points, respectively, assuming they are samples sampled from the edges of three distribution clusters. (Here, this is to facilitate the manual grouping of samples and magnify certain details. In reality, the samples would have thousands of dimensions, with the same issue present in each dimension.)

2.3.3. Summarize

In summary, the k -Nearest Neighbor Squared Distance Mean Score Calculation Function has obvious drawbacks when $k > 1$, but it exhibits better universality when $k = 1$. In most cases, particularly when it is highly probable that the sample is anomalous (anomaly detection tasks generally use the highest anomaly score sample from anomaly segmentation for further anomaly score calculation), this method does not produce the extreme errors seen in previous reweighting methods. The PatchCore

Anomaly Score Calculation Function can have better distribution patterns of anomaly scores in certain situations, but it imposes stringent requirements on the sampling method and the distribution of sampling results. When using the k NN distance metric to calculate the anomaly score, k needs to be smaller than the number of samples in the cluster, and the anomaly detection performance is best when k is close to the number of samples in the cluster. Accounting for the above visual analysis results, as shown in Equation 14, we define memory bank \mathcal{M}' as a set consisting of many clusters \mathcal{C} , each of which consists of k NN samples. In the equation, d should be defined based on empirical observations. Choosing a suitable k for each cluster in the anomaly scoring phase is noteworthy. However, for computational and implementation convenience, we simply assume that the k values of \mathcal{C} in \mathcal{M}' close to the abnormal samples of the test set are small, while the k values of other \mathcal{C} are large.

$$\begin{aligned} \mathcal{M}' = \{ & \\ & \mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_n \mid n \in \mathbb{Z}^+, \\ & (\forall c \in \mathcal{C}_n, \exists c' \in \mathcal{C}_n \setminus \{c\}, \text{dist}(c, c') \leq d), \\ & (\forall c \in \mathcal{C}_n, \forall c' \in \mathcal{M} \setminus \mathcal{C}_n, \text{dist}(c, c') > d) \\ & \} \\ \mathcal{M} = \bigcup_{\mathcal{C} \in \mathcal{M}'} \mathcal{C} \end{aligned} \quad (14)$$

We pay more attention to abnormal samples in the anomaly detection (AD) task, while normal samples are predominant in the anomaly scoring (AS) task. Therefore, we should set different values of k for anomaly score calculation in AD and AS. Specifically, a smaller k value is designed for AD anomaly score calculation, and a larger k value is designed for AS anomaly score calculation.

3. Experiments

3.1. Datasets

The **MVTec AD dataset** is a comprehensive benchmark dataset for evaluating anomaly detection algorithms in industrial inspection scenarios. It consists of over 5,000 high-resolution color images across 15 different object and texture categories. The dataset includes both normal images for training and validation, as well as anomalous images for testing, with various types of real-world defects such as scratches, dents, and contaminations. The objects and textures in the dataset exhibit a range of complexities and challenges for anomaly detection, making it a valuable resource for developing and assessing the performance of unsupervised and semi-supervised anomaly detection methods in the context of manufacturing and quality control[5,6].

The **MVTec-3D AD dataset** comprises 4,147 high-resolution industrial 3D scans across 10 object categories. It includes anomaly-free scans for training and validation, as well as test samples with various real-world anomalies like scratches, dents, and contaminations. The objects range from those with natural variations (bagel, carrot, cookie, peach, potato) to standardized but deformable ones (foam, rope, tire) and rigid ones (cable gland, dowel). The dataset is designed for unsupervised anomaly detection in industrial inspection scenarios, featuring 41 types of anomalies[40].

3.2. Evaluation Metrics

This work compares the I-AUROC[5,6] and P-AUROC[5,6] performance with PatchCore on the MVTec AD dataset, and with BTF and M3dM on the MVTec-3D AD dataset, with the P-AUROC (integration upper limit set to 0.3)[6,43,44].

3.3. Implementation Details

Our experiments were primarily conducted on the official GitHub repositories of PatchCore and BTF. Except for experimental variables and specifically mentioned parameters, all other param-

eters remained the same as the official defaults. Even during the performance comparison process, we abandoned many performance optimization techniques, with significant potential performance improvements.

When comparing the performance of AD&S on the MVTec-3D AD dataset using the BTM method with other approaches, we employed the parameter $k = 3$ as recommended in the PatchCore paper for the AS task in k NN squared distance mean metrics.

3.4. Performance Comparison

3.4.1. Anomaly Detection on MVTec-3D AD

To compare the anomaly detection (AD) performance, we evaluated BTM against several 3D, RGB, and RGB + 3D multimodal methods on the MVTec-3D dataset. As shown in Table 1, under the RGB + 3D multimodal setting, BTM exhibited an average AD performance improvement of 5.7% compared to the previous BTF method; this advantage was also observed in each individual category. In the RGB and 3D modalities, BTM achieved average performance improvements of 3.1% and 3.9%, respectively, over BTF; again, this improvement was consistent across each category.

We also replicated M3DM using the code and corresponding model parameters from the official GitHub repository. In comparing our results with the replication, our method demonstrated strong competitiveness overall. Specifically, in the RGB + 3D multimodal setting, BTM outperformed M3DM by 0.4%, achieving a performance of 93%. It is worth noting that unlike M3DM, we did not use manually designed foreground templates, leaving significant room for further AD performance enhancement. We prefer to validate the model by preserving the foreground and background to ensure its robustness.

3.4.2. Anomaly Segmentation on MVTec-3D AD

To compare the anomaly scoring (AS) performance, we evaluated BTM against several 3D, RGB, and RGB + 3D multimodal methods on the MVTec-3D dataset. As shown in Table 2, under the RGB + 3D multimodal setting, BTM achieved an average AUPRO performance of 96.9%, surpassing M3DM and BTF by 0.8% and 0.5%, respectively. This superiority was also evident when examining individual categories. In the RGB and 3D modalities, BTM outperformed BTF. It also shows strong competitiveness compared to other methods.

On the MVTec-3D dataset, BTM achieved an average P-AUROC performance of 99.5%, surpassing BTF and M3DM by 0.5% and 0.2%, respectively. Detailed P-AUROC performance comparisons are provided in Table 3.

Similarly, as we did not utilize manually designed foreground templates like M3DM or 3D-ST, we believe there is substantial room for AS performance improvement.

3.5. Performance of k NN Reweighting Metrics on BTF

We conducted experiments on computing AD anomaly scores using BTF with a k NN reweighting approach (Equation 11) on the MVTec-3D AD dataset. As shown in Figure 8, the AD performance is lowest when $k=1$. Subsequently, as k increases, the influence of weight w decreases, and the AD performance gradually approaches our optimal performance.

3.6. Performance of k Squared Distance Mean Metrics on BTF

We conducted experiments on computing AS anomaly scores based on k NN Squared Distance Mean Metrics using BTF on the MVTec-3D AD dataset. As shown in Figure 9, when $k=1$, the performance of P-AUROC and AUPRO is the lowest, and then, with the increase of k , the performance of P-AUROC and AUPRO reaches the maximum at $k=2$ and $k=3$ respectively, and then starts to decrease.

Table 1. I-AUROC score for anomaly detection of all categories of MVTec-3D AD. Our method clearly outperforms other methods in 3D + RGB setting and get 0.930 mean I-AUROC score.

* Denotes results obtained by employing pre-trained parameters provided by the original studies. Unannotated results are directly excerpted from the corresponding literature. Because the number of normal pixels overwhelmingly dominates in anomaly detection tasks, the importance of this metric has significantly diminished. Since 2021, AS tasks have primarily referenced the AUPRO metric.

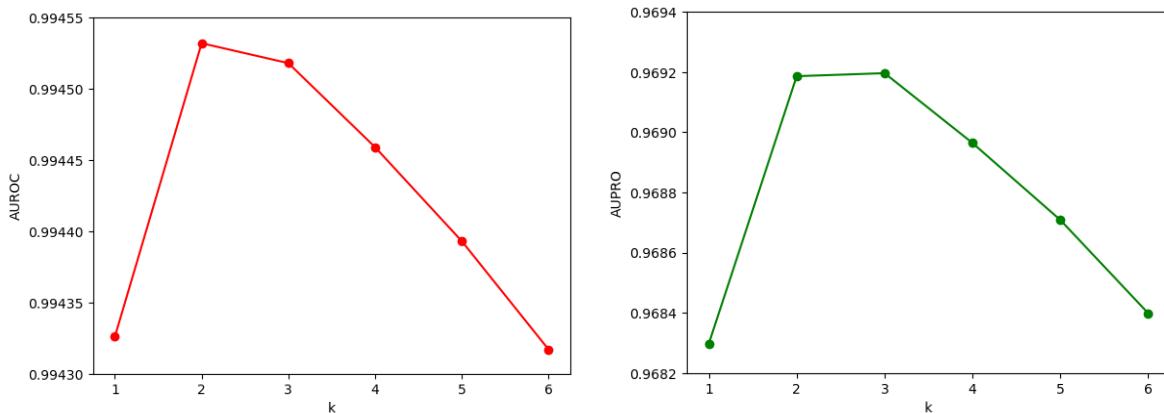

Figure 9. AD performance of kNN square distance mean metrics method on BTF.

3.7. Performance of kNN Squared Distance Mean Metrics on 2D Datasets with PatchCore Method

In this experiment, we used the official code and only modified the k value, keeping the evaluation metrics consistent with those in the original paper.

As shown in Figure 10, this work tests the impact of different k values on the anomaly detection and segmentation performance of PatchCore on the MVTec AD dataset (using the mean of squared distances to calculate anomaly scores).

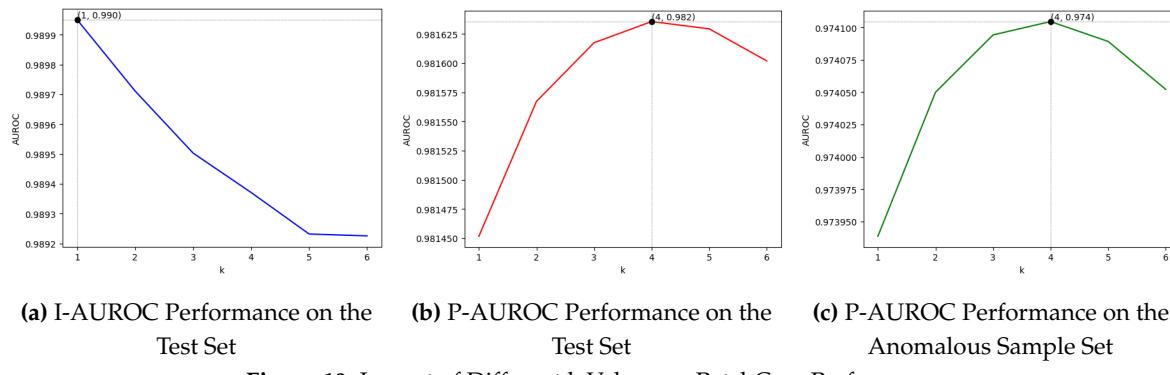

Figure 10. Impact of Different k Values on PatchCore Performance

As shown in Figure 10a, for the anomaly detection task, the algorithm performs best when $k = 1$; as k increases, the detection performance declines. As shown in Figures 10b and 10c, the algorithm's segmentation performance is poor when $k = 1$; as k increases, the segmentation performance first improves and then declines, achieving the best segmentation performance at $k = 4$.

It is noteworthy that compared to the segmentation results in Figure 10b, which exclude normal samples (anomalous samples also have many normal pixels), the performance decline after reaching the peak value in Figure 10c is noticeably more gradual. This further supports the view that anomaly detection metrics require smaller k values.

4. Discussion

In Section 2.3, we analyze the kNN distance metric score distribution gradient. Through this, we find that k needs to be smaller than the number of samples in the cluster (defined in Equation 14) when calculating the anomaly score using the kNN distance metric. Anomaly detection performance is best when k is close to the number of samples in the cluster. Based on this finding, we design a simple anomaly score calculation method based on BTF, which uses different kNN metrics in AD and AS phases respectively, and name it BTM in Section 2.1. It is worth noting that more complex distance measures are worth further research. At the same time, when studying the distance metric, we should also consider the impact of the memory bank sampling method on the distance metric.

In Section 3.4, we verify the effectiveness of BTM through experiments on the real dataset MVTec-3D AD. BTM achieves excellent performance (I-AUROC 93.0%, AURPO 96.9%, P-AUROC 99.5%) ahead of the BTF method (I-AUROC 5.7% \uparrow , AURPO 0.5% \uparrow , P-AUROC 0.2% \uparrow). Without using foreground masks (manually created binary masks), BTM is still highly competitive compared to other state-of-the-art methods using manual foreground masks.

In sections 3.5 and 3.6, we further analyze the effect of different k values on the two distance measures and the different effects of various k values on the AD and AS tasks using real datasets. We further verify our conjecture in Section 2.3.

5. Conclusions

Different "clusters" have different requirements for the k value in kNN distance metrics. AD and AS tasks have different requirements for the value of k in the kNN distance metric. We designed the BTM method based on the BTF and performed experiments on MVTec-3D AD to verify this. We also call for further research on "More complex Distance Measures" and "The Impact of memory bank's Sampling Method on Distance Measures".

Future work could consider the robust kNN methods proposed in recent studies. Rousseeuw and Hubert [50] suggest using robust statistics to enhance kNN by fitting the majority of the data and

flagging outliers, while Li et al. [51] propose improvements to kNN to better handle various data distributions. These approaches can serve as valuable references for enhancing kNN-based anomaly detection methods.

Appendix A. Formula Mentioned in the Original Article of PatchCore

The following equations are subject to ongoing debate, and their implementation has not been publicly disclosed by the authors. Additionally, public inquiries regarding these equations from June 15, 2022, remain unanswered [52,53]. Current academic work related to this can be summarized by equations 3, 4, 5, 6, and 7 in the paper, which conflict with the cited equations. Including these equations in the main text may cause further confusion and conflict.

Appendix A.1. Expressed in the Original Article

$$(m^{test,*}, m^*) = \arg \max_{m^{test} \in \mathcal{P}(x^{test})} \arg \min_{m \in \mathcal{M}} \|m^{test} - m\|_2 \quad (A1)$$

$$s^* = \|m^{test,*} - m^*\|_2$$

Appendix A.2. Expressed in Our Context

$$(f_{i^*,j^*}, m^*) = \arg \max_{f \in F} \arg \min_{m \in \mathcal{M}} \|m - f\|_2 \quad (A2)$$

$$s^* = \|m^* - f_{i^*,j^*}\|_2$$
