**Abstract:** **Background:** The Risk of Paradoxical Embolism (RoPE) score was developed to identify stroke-related patent foramen ovale (PFO) in patients with cryptogenic stroke. **Methods:** We conducted a retrospective analysis of the 2016 to 2020 National Inpatient Sample to determine the performance of modified RoPE score for PFO presence in patients with acute ischemic stroke (AIS). **Results:** A total of 3,338,805 hospital admissions for AIS were analysed and 3.0% had PFO. Patients with PFO were younger compared to those without PFO (median 63 years vs. 71 years,  $p<0.001$ ) and fewer were female (46.1% vs. 49.7%,  $p<0.001$ ). The patients with PFO had greater mean modified RoPE score (4.0 vs. 3.3,  $p<0.001$ ). The area under the curve for the RoPE score in predicting PFO was 0.625 (95%CI 0.620-0.629). The best diagnostic power of the RoPE score was achieved with a cut point of  $\geq 4$  where the sensitivity was 55% and the specificity was 64.2%. A cut point of  $\geq 5$  increased specificity (83.1%) at the expense of sensitivity (35.8%). The strongest predictor of PFO was deep vein thrombosis (OR 3.97, 95%CI 3.76-4.20). **Conclusions:** The modified RoPE score had modest predictive value in identifying patients with PFO among patients admitted with AIS.

**Keywords:** acute ischemic stroke; AIS; cryptogenic stroke; patent foramen ovale; PFO; RoPE score; risk of paradoxical embolism; risk stratification; prediction;

## 1. Introduction

Patent foramen ovale (PFO) is the most common congenital heart abnormality of foetal origin that is present in approximately 25% of the worldwide adult population [1]. It holds clinical relevance since PFO is a highly prevalent finding in cryptogenic ischemic stroke, particularly among younger adults [2]. A case-control study of 60 adults under 55 years of age with ischemic stroke matched to a control group of 100 patients found that PFO was present in 40% of patients with ischemic stroke compared to 10% of controls [3]. A subsequent prospective evaluation of 227 patients with cryptogenic stroke and 276 control patients with stroke of known cause found that the odds of PFO were significantly greater for patients with cryptogenic stroke for both younger patients (OR 4.70,

95%CI 1.89-11.68) and older patients (OR 2.92, 95%CI 1.70-5.01) [4]. A meta-analysis of 15 studies revealed that PFO presence was associated with an increase in odds of ischemic stroke compared to controls (OR 1.83, 95%CI 1.25-2.66) [5]. There is therefore a great interest in predicting PFO among patients with ischemic stroke since there is a growing evidence that PFO closure may reduce the risk of recurrent stroke in carefully selected young cryptogenic stroke patients [6].

The Risk of Paradoxical Embolism (RoPE) score was derived from 12 component studies to determine the likelihood that a stroke was related to PFO [7]. The score consists of 6 variables with a maximum score of 10 points. In the derivation study it was found that among patients with 0 to 3 points, PFO existed in 23% of patients to 73% prevalence of PFO in patients with scores of 9 or 10 [7]. In the validation study, using a cut-off of 7 points with area under the curve of 0.704, there was a sensitivity of 69.4% and specificity of 62.5% and RoPE score >7 was significantly associated with greater PFO frequency (53.6% vs. 10%) [8]. Using data from three clinical trials of PFO closure, the RoPE score identified patients with cryptogenic stroke who are likely to have a PFO that is pathogenic rather than incidental [9].

Whether or not the RoPE score can be used to predict patients with PFO among patients with ischemic stroke from a large and real-world nationwide patient sample is unknown and has not been yet explored. For these reasons, in the present study, we examined the predictive value of a modified RoPE score to identify PFO in patients with ischemic stroke from the large and representative nationwide database in the United States - the National Inpatient Sample (NIS).

## 2. Materials and Methods

This manuscript was prepared in accordance with the recommendations of the STROBE criteria [10].

### *Ethics and Approvals*

Institutional review board approval for the study was not required for analysis of data from that National Inpatient Sample [11].

### *Dataset*

We analyzed data from the NIS between 2016 to 2020. The NIS is the largest all-payer inpatient care database in the United States which is produced by the Healthcare Cost and Utilization Project (HCUP) at the Agency for Healthcare Research and Quality (AHRQ). The NIS samples hospital admission data from approximately 20% of the samples of hospitals in the United States which translates to 5 to 8 million hospital admissions from approximately 1,000 hospitals. It contains more than 100 clinical and non-clinical variables including diagnostic codes, procedure codes, patient demographics and patient admission and discharge status. The data from the NIS can be weighted to generate national estimates.

### *Variable Definition*

We used International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM) primary diagnosis codes I63 to identify the hospital admissions where patients were diagnosed with acute ischemic stroke. The modified RoPE score was defined by a history of hypertension, history of diabetes, history of stroke or TIA, smoker and age excluding cortical infarct on imaging. Each variable aside from age was assigned one point for yes and age was scored up to 5 points (18-29 years 5 points, 30-39 years 4 points, 40-49 years 3 points, 50-59 years 2 points, 60-69 years 1 point and  $\geq 70$  years 0 points). The exclusion of the cortical infarct on imaging was applied because our cohort was patients with hospital admission for acute ischemic stroke which likely had cortical infarction on imaging. The modified RoPE score was scored from 0 to a maximum score of 9.

Clinical comorbidity variables for each admission were determined based on the ICD-10 codes or data available in the NIS as defined in Supplementary Table S1. We identified the following neurological deficits using ICD-10-diagnosis codes: aphasia (I69.320, I69.920, R47.01), hemiplegia

(I69.35, G81), neglect (R41.4), somnolence, stupor, and coma (R40), dysphagia (R13.1), and homonymous hemianopsia (H53.46) as indicators of neurological severity. We also evaluated the proportion of patients admitted to the teaching and non-teaching hospitals, and those admitted to rural hospitals. In the NIS database, the hospital's location and teaching status were obtained from the American Hospital Association Annual Survey of Hospitals. A metropolitan statistical area is considered urban, and a non-metropolitan statistical area is rural. Teaching hospitals have an AMA-approved residency program or have membership in the council of teaching hospitals. The hospital bed sizes were classified in the NIS database into three subgroups (small, medium, or large) based on the location and teaching status of the hospital. Patients undergoing interhospital transfer were identified using the "TRAN\_IN" variable. Intracranial hemorrhage was defined as a composite of intracerebral or subarachnoid hemorrhage as identified using ICD-10-CM codes I60, I61, and I62.9.

The main outcome measure for this analysis was the presence of PFO defined by the ICD-10 diagnosis code Q21.1. We also assessed for whether patients were discharged home or died in-hospital based on the "DISPUNIFORM" variable. The full description of all the variables and codes are shown in Supplementary Table S1.

#### *Statistical Analysis*

Statistical analysis was performed on STATA 13.0 (College Station, TX, USA). Descriptive statistics were presented for the patient characteristics, management and outcomes stratified by the presence or absence of PFO. For continuous variables the median and interquartile range were presented and the median test on Stata was used to determine if there were statistical differences between the group with and without PFO. Categorical variables were described with percentages and the Chi<sup>2</sup> test was used for determining if there were differences for the group with PFO. The modified RoPE scores for the cohort according to presence or absence of PFO is shown graphically and in a table. The Stata function "ROCTAB" was used to perform nonparametric ROC analysis which enabled evaluation of the sensitivity and specificity at different cut points of modified RoPE score and graphical presentation of the ROC and the area under the curve (AUC). Multiple logistic regression was performed to identify the independent predictors of PFO with patient demographic, hospital, comorbidities, and severity markers as candidate variables in the multivariable adjusted model.

### **3. Results**

A total of 3,351,630 patients with hospital admissions for the principal diagnosis of acute ischemic stroke were identified in the National Inpatient Sample between 2016 to 2020. After excluding 12,825 patients who were of age less than 18 years, a total of 3,338,805 hospital admission for acute ischemic stroke were included in the analysis of which 101,290 (3.0%) had a PFO.

The patient characteristics, management, and outcomes for the patients with admission for acute ischemic stroke according to the presence of PFO is shown in Table 1. Patients with PFO were younger compared to those without PFO and fewer were female. Those with PFO were in lesser proportion receiving Medicare and greater in proportion in having private insurance or self-paying. A greater proportion of patients with PFO were admitted to hospitals with large bed size and to teaching hospitals. Patients with PFO were less likely to have hypertension, diabetes mellitus, congestive heart failure, chronic kidney disease, and dementia. Similarly, patients with PFO had greater prevalence of DVT compared to patients without PFO. In terms of hospital management, patients with PFO were more likely to have hospital transfer, thrombolysis, mechanical thrombectomy, and PFO closure. In addition, patients with PFO were in greater proportion discharged home, and less likely to die in hospital.

**Table 1.** Characteristics, management, and outcomes for patients with acute ischemic stroke according to the presence or absence of patent foramen ovale (PFO).

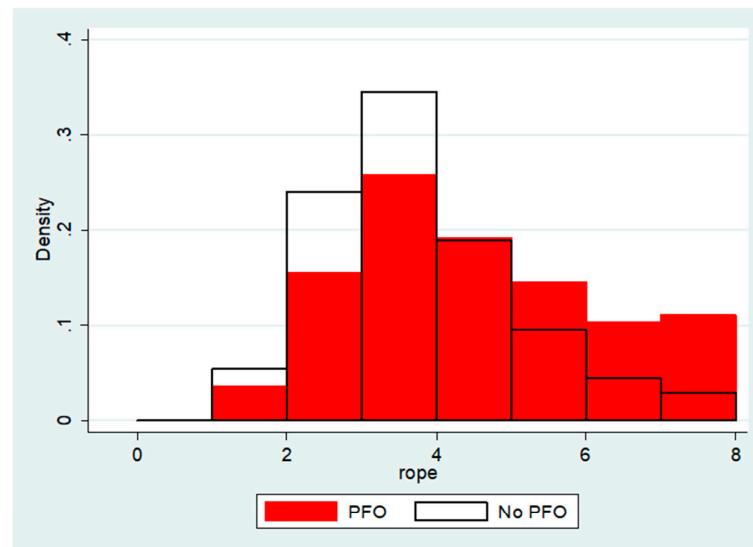

Variable	No PFO (n=3,237,515)	PFO (n=101,290)	p-value

**Abbreviations:** IQR=interquartile range.

*RoPE Score*

The patients with PFO had a significantly greater mean modified RoPE score (4.0 vs. 3.3,  $p<0.001$ ) and median modified RoPE score (4 vs. 3,  $p<0.001$ ), compared to patients without PFO as shown in **Figure 1**.

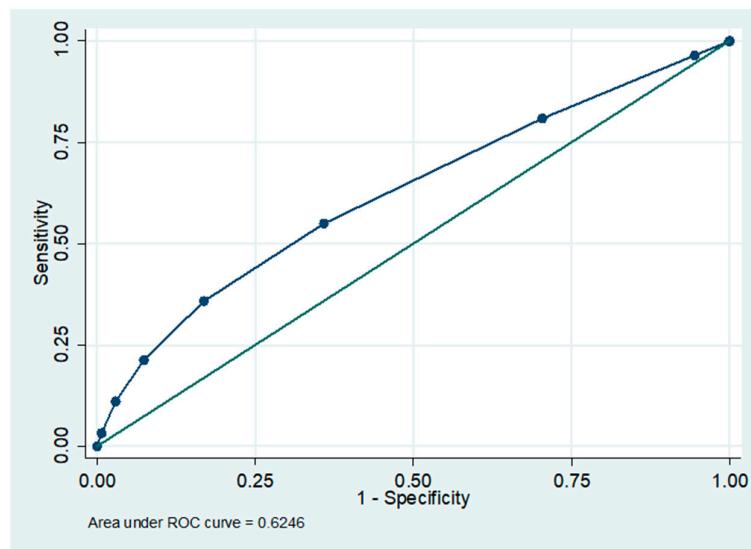

ROPE score	0	1	2	3	4	5	6	7	8
PFO	<0.1%	3.6%	15.5%	25.9%	19.2%	14.5%	10.3%	7.8%	3.3%
No PFO	<0.1%	5.5%	24.1%	34.6%	18.9%	9.5%	4.5%	2.2%	0.7%

PFO=patent foramen ovale

**Figure 1.** The distribution of RoPE scores according to PFO presence or absence.

The area under the curve (AUC) for the modified RoPE score in predicting PFO among patients with acute ischemic stroke was 0.625 95%CI 0.620-0.629, as depicted in Figure 2.

Cutpoint	Sensitivity	Specificity	Correctly classified
≥0	100.0%	0%	3.0%
≥1	100.0%	<0.1%	3.1%
≥2	96.4%	5.5%	8.3%
≥3	80.9%	29.6%	31.2%
≥4	55.0%	64.2%	63.9%
≥5	35.8%	83.1%	81.7%
≥6	21.3%	92.6%	90.5%
≥7	11.1%	97.1%	94.5%
8	3.3%	99.3%	96.4%

**Figure 2.** Area under the curve (AUC) analysis showing sensitivities and specificities for PFO presence according to the points aggregated by the RoPE score.

The optimal balance of sensitivity was achieved with a cut point of  $\geq 4$  where the sensitivity and specificity for PFO presence were 55.0% and 64.2%, respectively. Sensitivity could be improved by using a cut point of  $\geq 3$  (80.9%) but there was a trade-off reduction in specificity (29.6%). Similarly, using a cut point of  $\geq 5$  increased specificity (83.1%) at the expense of sensitivity (35.8%).

#### Multivariable Regression Analysis

Variables independently associated with PFO presence that were derived from multivariable-adjusted logistic regression analyses are shown in Table 2.

The strongest independent predictors of PFO presence were deep vein thrombosis (OR 3.97, 95%CI 3.76-4.20,  $p<0.001$ ), atherosclerosis of the aorta (OR 2.35, 95%CI 2.14-2.58,  $p<0.001$ ), teaching hospital status (OR 1.50, 95%CI 1.44-1.56,  $p<0.001$ ) and homonymous hemianopsia (OR 1.43, 95%CI 1.33-1.54,  $p<0.001$ ).

Several variables were associated with a reduction in odds for PFO including age (OR 0.97, 95%CI 0.97-0.97,  $p<0.001$ ), arterial hypertension (OR 0.71, 95%CI 0.68-0.73,  $p<0.001$ ), diabetes mellitus (OR 0.71, 95%CI 0.69-0.74,  $p<0.001$ ) and palliative care (OR 0.57, 95%CI 0.53-0.61,  $p<0.001$ ).

**Table 2.** Multivariable predictors of patent foramen ovale (PFO) presence.

Variable	Odds ratio (95%CI)	p-value

#### 4. Discussion

This large nationwide and real-world observational analysis provides several key findings. First, in the national settings in the United States, 3% of patients with ischemic stroke are found to have PFO. Second, the patients with ischemic stroke who have PFO are different from those without PFO as they are younger and less comorbid. Third, the modified ROPE score provided only modest predictive value for PFO among ischemic stroke patients. Finally, the strongest predictor of PFO in patients with stroke was DVT which was associated with a four-fold increase in the odds of PFO. These findings suggest that the modified ROPE score is predictive of PFO in patients with acute ischemic stroke but not as highly predictive as in some previous validation studies.

The RoPE score places great emphasis on age as well as other factors which are not known to be associated with PFO. A review suggest that the main risk factors linked with PFO-attributed strokes are young age, PFO size, right-to-left shunt degree, PFO morphology, presence of atrial septal aneurysm, intrinsic coagulation-anticoagulation systems imbalance, and co-existence of other atrial abnormalities, such as right atrial septal pouch, Eustachian valve and Chiari's network [12]. Among the non-age factors in the RoPE score, the previous stroke or TIA and smoking merit discussion. A meta-analysis for 14 studies suggests that medically treated patients with PFO do not have higher risk for recurrent cryptogenic cerebrovascular events, compared with those without PFO [13].

However, the fact that is a recurrent stroke risk raises the question of whether treatment of the PFO could have prevented the subsequent stroke. There is evidence that tobacco smoking induces a systemic hypercoagulable state [14]. However, the smoking variable in the models treat the variables simply in a binary manner, and does not consider differences between current smokers and ex-smokers together nor the duration of smoking and amount that was smoked (pack-years). Nevertheless, the RoPE score should be considered in the choice of therapy decision-making for PFO according to a European positional paper for the management of PFO [15].

The finding that DVT is the strongest predictor of PFO in the ischemic stroke cohort is not surprising. DVT in the leg might embolize from the venous circulation and cross via the PFO into the arterial circulation causing embolic ischemic stroke. However, patients with stroke may also have hemiplegia which may predispose their risk of developing DVT. A systematic review suggests that the incidence of DVT varies from 2% to 10% after an acute stroke and death from pulmonary embolism can account for 13% to 2% of early deaths [16]. In the current dataset, we know that both pathologies occurred, but we do not know the temporal sequence of pathology. This can be challenging to determine as one study suggests that up 17.6% of patients with acute stroke have a DVT on admission for acute stroke [17]. Also, the etiology of DVT involves Virchow's triad of stasis, hypercoagulability and endothelial injury which may also acts as precipitating factors of acute ischemic stroke [18]. Even in the event of a clinical DVT manifesting after a stroke it could have started before the onset of stroke. In addition, it is unknown whether patients who have a stroke as a result of paradoxical embolism are at increased risk of venous thromboembolism complicating their stroke. If there is such as increased risk of venous thromboembolism complicating a stroke related to paradoxical embolism, there may be benefit of using anticoagulation rather than antiplatelet medications in these patients but this needs evaluation by future studies.

An unexpected observation was the association between atherosclerosis of the aorta and PFO. It is unclear why there is this association and the possible mechanism so more studies are needed.

From a clinical perspective, the finding of a PFO is often an incidental finding as it is common but the question of whether anything should be done about a PFO once found is clinically relevant. If a patient would not have a change in management if a PFO was found, the patient should not undergo testing for it. The closure of the PFO is now an established percutaneous procedure but undertaking the procedure should have strong evidence favoring patient benefit because the procedure carries procedural and periprocedural risk. The Society of Cardiovascular Angiography and Intervention (SCAI) guidelines suggest that PFO closure should be preferred over medical therapy alone in persons with systemic embolism without a prior PFO-associated stroke in whom other embolic etiology have been excluded and in patients between ages of 18 to 60 years as well as those over age of 60 years with prior PFO-associated stroke [19]. In addition, these guidelines suggests that RoPE score of  $\geq 7$  may identify patients who are likely to receive greater benefit from PFO closure. The European positional paper states that percutaneous closure of PFO can be performed in carefully selected patients aged 18 to 65 years with a confirmed cryptogenic stroke, systemic embolism, and an estimated high probability of a causal role of the PFO as assessed by clinical, anatomical, and imaging features [20]. This statement also mentions the RoPE score as a tool which may be useful but there are no large external validation studies supporting its use.

In the present study, we utilized the National Inpatient Sample data in attempt to validate the modified RoPE score and we found that it does not perform as well as previous validation studies for predicting PFO in cryptogenic stroke. One possible reason for this may be that this cohort lacks the granular detail to determine what proportion of stroke did not have an identifiable cause and the inclusion of those with identifiable precipitants for stroke may explain its modest predictive results for PFO. Selection biases in real-world testing for PFO may explain some of the findings of the current studies. We found that younger patients and those with private insurance were more likely to have PFO. This may reflect greater use of testing for PFO among younger patients and those who have their care paid for by insurance. The lower proportion of patients with dementia in the PFO group may reflect the younger population with PFO. It is notable that there may be undertesting of PFO in the study as the overall rate of PFO of 3% is low, but the cohort is not exclusively patients with cryptogenic stroke.

#### *Strengths and Limitations*

This study has several strengths and limitations. The strength of the current evaluation is that it represents a large contemporary real-world ischemic stroke population that is nationally representative data from the United States. Also, we were able to evaluate many different variables which are clinically relevant for patients with acute ischemic stroke. The first limitation is that we do not have imaging data, so we had to modify the original RoPE score as one of the variables was cortical infarcts on imaging. However, we suspect that the vast majority of the patients included had cortical infarcts on imaging as they all had a discharge diagnosis of acute ischemic stroke. The second key limitation is that the extent to which PFO was investigated for in the cohort is not known. For patients to have a diagnosis of PFO on their discharge summary together with acute ischemic stroke, it is likely that the diagnosis was based on an imaging procedure as opposed to a clinical diagnosis. However, what is unclear is how often imaging was undertaken to look for PFO when more common causes for stroke were identified such as atrial fibrillation, carotid dissection or carotid, cerebral, vertebral, or basilar artery stenoses. Moreover, there may be biases in the investigation for PFO because only those who may be candidates for PFO closure might undergo testing. As a result, this study may under capture the true number of cases of PFO in the cohort as not all patients may have been tested.

## 5. Conclusions

In this nationally representative data from the United States, we found that the modified RoPE score provided a modest predictive value in identifying PFO presence among patients admitted with an ischemic stroke. The strongest predictor of PFO in real-world settings of acute stroke patients was DVT. More studies are needed to determine how the RoPE score may have value in the selection of patients who may benefit from investigations for PFO and PFO closure from real-world settings.
